Seismicity and Focal Mechanisms for the Southern Great Basin of Nevada and California: 1987 through 1989

Abstract

For the calendar year 1987, the southern Great Basin seismic network (SGBSN) recorded about 820 earthquakes in the southern Great Basin (SGB). Local magnitudes ranged from 0.2 to 4.2 (December 30, 1987, 22:50:42 UTC at Hot Creek Valley). Five earthquake epicenters in 1987 within the detection threshold of the seismic network are at Yucca Mountain, the site of a potential national, high-level nuclear waste repository. The maximum magnitude of those five earthquakes is 1.1, and their estimated depths of focus ranged from 3.1 to 7.6 km below sea level. For the calendar year 1988, about 1280 SGB earthquakes were catalogued, with maximum magnitude 4.4 for an Owens Valley, California, earthquake on July 5, 1988. Eight earthquake epicenters in 1988 are at Yucca Mountain, with depths ranging from three to 12 km below sea level, and maximum magnitude 2.1. For the calendar year 1989, about 1190 SGB earthquakes were located and catalogued, with maximum magnitude equal to 3.5 for an earthquake about ten miles north of Las Vegas, Nevada, on January 9. No Yucca Mountain earthquakes were recorded in 1989. An earthquake having a well-constrained depth of about 30 km below sea level was observed on August 21, 1989, in eastern Nevada Test Site (NTS).

The greatest concentration of SGB earthquakes in a small area during the three years 1987 through 1989 occurred at the Reveille Range (Reveille Peak quadrangle), about 115 km north of Yucca Mountain. Other concentrations of seismicity were observed at Rock Valley (southern Nevada Test Site), Pahranagat Shear Zone, Sarcobatus Flat, Gold Flat, and in the Grapevine Mountains. Seismicity near Boulder City, Nevada and Lake Mead produced very modest structural damage at Boulder City. The magnitude 3.5 earthquake in January, 1989, near Las Vegas, Nevada, resulted in a few cracked windows at Las Vegas, the only other case of damage being reported from earthquakes in the southern Great Basin for that three-year period.

Focal mechanisms from thirty-one SGB earthquakes are presented in this report. The solutions range from normal slip or oblique slip to strike slip, with a few having sub-horizontal nodal planes. Tension axes for most SGB earthquake focal mechanisms cluster in the northwest-southeast direction, and tend to display sub-horizontal angles of inclination. Alternate focal mechanism solutions resulting from different assumed hypocenters demonstrate that, in some instances, the current seismographic network cannot provide unambiguous focal mechanism solutions, even for some of the magnitude > 3 earthquakes. This is because the focal mechanism is dependent on depth of focus, which is often a poorly resolved parameter.

Examination of travel-time delays for P waves from NTS nuclear tests indicates a strong 180° azimuthal pattern, especially for data from Rainier Mesa and western Yucca Flat tests. This pattern could be the signature of stress-induced and/or crack-induced azimuthal velocity anisotropy, or alternatively, of a high-speed body having a longitudinal axis oriented approximately north 10° east to south 10° west, possibly the lower carbonate aquifer. Whatever the source, delays have no significant correlation with distance, probably indicating the presence of localized tectonic or geologic anomalies (radius < 50 km) rather than a regional feature.

Introduction

The SGBSN, one of several regional seismographic networks operating in the Great Basin, has monitored local seismicity and has recorded arrivals from regional and teleseismic earthquakes continuously since August, 1978. 54 permanent stations were in place by mid-1981, including a dense sub-array at Yucca Mountain, Nevada. Preliminary hypocenter listings and seismicity data analysis from data collected by the SGBSN for the period August, 1978 through December, 1986, are presented in Rogers and others (1987) and Harmsen and Rogers (1987). This report is an addendum/update to those reports. A broad-scope review of the seismotectonics of Nevada is available in

Rogers and others (1991), where contemporary SGB and other seismicity data are discussed in the context of the Cenozoic deformation of the Great Basin.

The SGBSN was initially composed entirely of vertical-component seismographic stations. Eight horizontal-component seismographs were added in 1984, and a vertical-component seismograph south of Boulder City, Nevada, was added in August, 1988. Figure 1 shows the seismic station locations and major physiographic structures discussed below. Appendix E lists station parameters. References to individual stations in the text below will be in **bold** font.

The primary purpose of the network is to investigate the seismotectonic environment in the immediate vicinity of Yucca Mountain, Nevada, the potential site of a high-level, national nuclear waste repository. Also, the network provides information on seismicity at greater distances, out to about 160 km radial distance of Yucca Mountain. Seismic signals from the network are continuously telemetered to the USGS data processing center in Golden, Colorado, where preliminary hypocenter determination is performed, along with research on focal mechanisms and faulting, on fluid-induced seismicity, on attenuation of seismic waves, on velocity structure, on crustal strain in the southern Great Basin, and other topics having relevance to the Yucca Mountain Project.

Operation of the seismic network is funded under an interagency agreement with the Department of Energy, which provides Quality Assurance regulations for the collection, analysis, interpretation, reporting and archiving of data. Digital, event-oriented SGBSN data (seismograms, station data, and so on) are permanently archived on magnetic tapes, and a nearly continuous record of analog SGBSN data is also maintained on 16 mm developcorder film. Because seismic data in the SGB come from sources and crustal paths that exhibit large degrees of geologic variability, with many details that are simply unknown, the hypocenters and analyses that are presented in open-file format must be considered preliminary. Uncertainty in many reported parameters, such as those associated with earthquake location and focal mechanism, is in most cases substantial and difficult to completely quantify. In this report, consequences of uncertainty are explicitly addressed by offering alternate hypocenters and focal mechanisms that are of comparable "goodness-of-fit" within the context of the simplified geologic models invoked to parametrize the earth. Since a possible consequence of this high level of ambiguity is that permissible licensing uncertainties about the seismotectonic component of the geologic system may be exceeded, as stipulated in 40 CFR Part 191, the U.S.G.S. response is to increase the density of seismic station coverage of southwestern Nevada during the next few years, with the expectation of reducing parameter estimate uncertainties for much of the recorded local seismicity.

Acknowledgments

Maintenance and periodic calibration of seismographs and related field equipment is performed by D. E. Overturf of the U. S. Geological Survey, and by contract technicians. Arrival time and amplitude data from earthquakes and blasts were initially scaled by Pingsheng Chang, a contract technician, and by Miles Weida and Mark Meremonte, of the U.S. Geological Survey.

The seismological laboratories of the University of Utah at Salt Lake City (UUT), the University of Nevada at Reno (REN), the California Institute of Technology at Pasadena (PAS), the USGS at Menlo Park, California (MNLO), and the National Earthquake Information Center at Golden, Colorado (NEIC), provided useful seismograms, first motion data, and/or magnitude estimates for several of the earthquakes discussed in this report.

Helpful reviews of this report were provided by David M. Perkins and Henri S. Swolfs of the U.S. Geological Survey, Branch of Geologic Risk Assessment. The manuscript benefited from suggestions and section reviews by R. E. Anderson, J. Gomberg, and K. F. Fox.

Calibration procedures and results

A complete discussion of the technical procedures used in field calibrations of SGBSN stations is presented in the Quality Assurance document, YMP-USGS Seismic Procedure 11. Seismometers

Figure 1.— Map of SGBSN seismograph station locations, cities and towns, and some major physiographic features of the southern Great Basin.

are visited and calibrated every six months, or as needed. A station calibration is deemed acceptable when the amplitude response of a seismographic system lies within a $\pm 30\%$ range of a nominal response, in the frequency band $2 \leq f \leq 10$ Hz. In practice, seismographs with Teledyne-Geotech S13 seismometers generally display responses within $\pm 10\%$ of their nominal (theoretical) values in the frequency band $0.1 \leq f \leq 20$ Hz during field calibrations. Seismographs with Mark L4C seismometers generally display responses within $\pm 20\%$ of their nominal values in the frequency band $1 \leq f \leq 10$ Hz. Whenever measured responses deviate beyond the prescribed limits, a notation is made in a log of station calibrations, the field technicians are informed, and maintenance is performed on the defective component(s). The system is then recalibrated until its amplitude response falls within the prescribed limits. Calibration results are *not* currently used to correct or modify amplitude data scaled from SGBSN seismograms in order to estimate SGB earthquake magnitudes.

An upgrade seismic network, composed primarily of three-component S13 seismographs with much wider dynamic range than the current network, and digital satellite telemetry, is currently being deployed in the SGB. This network is expected to provide a more accurate measure of ground vibrations than the current network.

Preliminary hypocenter determination for SGB earthquakes and explosions

Earthquakes, explosions, and low-coda-frequency seismic phenomena (e.g., some cavity collapses and some nuclear detonation aftershocks) occurring in the southern Great Basin are located with HYPO71, and listed in Appendices A, B, and C, respectively. The SGB velocity models and other pertinent parameter information are listed in Appendix F. HYPO71 (Lee and Lahr, 1975) employs several iterative algorithms, some of which perform forward modelling; i.e., ray tracing in a simplified geologic medium to determine T_c , the computed source-to-station travel time. Others perform inverse modelling, in which a trial hypocenter is assumed at some position, and new solutions are found that move the trial hypocenter in a direction that reduces the root-mean-square travel-time residual, RMS . The definition of RMS is,

$$RMS = \sqrt{\frac{1}{n} \sum_i w_i (T_o - T_c)_i^2},$$

where n is the number of phase arrival time readings used in the determination (as discussed below, approximately 20% of the arrival time picks are not used in the final location), T_o is the “observed” source-to-station travel time (scaled arrival time – computed origin time) and w_i is the computed weight for the i th reading, with $\sum_i w_i = n$. Ideally, iterations towards a final solution continue until no significant reductions in RMS can be achieved by further adjustments. The directions/amplitudes of adjustments are determined by a Newton-Raphson scheme, known to seismologists as Geiger’s method. In the absence of “noise” or errors in the velocity model, or in the data, the method is both fast and accurate. Even in the presence of moderate Gaussian-distributed noise in the data, the method continues to perform satisfactorily. In the real world, however, pitfalls of the method are known to exist. One shortcoming of the iterative scheme is that it is apt to converge to a local minimum of the RMS function, rather than the global minimum, depending on the initial trial hypocenter, (x_0, y_0, z_0) . To partly ameliorate this problem, hypocenters for all earthquakes reported in Appendix A were relocated using different values of $z_0 = 0.0, 7.0$, and 12.0 km below sea level, respectively, selecting for reporting here the final iterate (x_f, y_f, z_f) having the minimum RMS residual. In the catalog, immediately following the two letter grades, the hypocenter is tagged with the letter “Z,” “S,” or “T,” depending on whether the solution having the minimum RMS was derived from iterations having starting depth of zero km, seven km, or twelve km below sea level, respectively.

If different final iterates yield the same RMS residual (± 0.005 sec), the hypocenter corresponding to the initial $z_0 = 7.0$ starting depth is selected for publication. This selection process may appear

arbitrary, but statistically, has little effect on the overall depth-of-focus distribution. We define $RMS(k) = RMS|z_0 = k$ km, and similarly, depth estimate, $z(k)$, and standard error in depth estimate, $stz(k)$. We investigated the percentage of hypocenters listed in Appendix A, below, that were derived from $z_0 = 7$ or 12 km iterations, but which also have competing solutions within $\approx 10\%$ of the sampled travel time residual minimum, $RMS(0) - RMS(k) \leq \max(0.01, 0.1 \min(RMS(k)))$ sec, $k = 7$ or 12 km. For the hypocenters of 1987, 570 hypocenters met this criterion. However, all but 92 of those 570 had the property that the depth estimate, $z(0)$, was within one standard error in depth of the reported depth estimate, $|z(k) - z(0)| \leq stz(k)$. Of the remaining 92, 49 competing depths were within two standard errors, $|z(k) - z(0)| \leq 2stz(k)$ (case A). The remaining 43 competing depths were greater than two standard errors from the reported depth of focus, $|z(k) - z(0)| > 2stz(k)$ ($\approx 5\%$ of the catalog, case B). In Appendix A, hypocenters having misleadingly low stz estimates are flagged by a + sign to the right of stz for case A, or by ++ for case B. This procedure conforms to the tradition of providing point estimates for hypocenters in preliminary seismicity catalogs, but explicitly acknowledges cases where depth-of-focus uncertainty is clearly underestimated by HYPO71's standard error statistics.

A more comprehensive solution than that outlined above would describe the volume where the RMS function (or a similar function) approximately attains its minimum. In general, it is emphatically *not* the case that the point estimate \pm one standard deviation is a reliable estimate of that volume, whether using HYPO71 or any similar least-squares software for hypocenter determination. One source of "undeserved optimism" regarding error estimates is that their statistical determination is based on the *local* behavior of RMS , which in some instances may display a steep-flanked trough at a depth corresponding to a local minimum, but which may display a broad, featureless minimum at another competing depth. In other instances the standard error estimate for focal depth may be unrealistically large, as occurs when the hypocenter locates in the immediate vicinity of the deepest sampled layer interface in the earth model.

The RMS travel time residual function is multivariate, and algorithmic attempts to minimize RMS are necessarily performed in lower-dimensional subspaces than its true domain. As a practical matter, hypocenter determination is performed by fixing many of these variables at "plausible" values, rather than routinely exploring all "equally likely" alternate values. In particular, RMS is obviously sensitive to weighting schemes, w_i , as well as to velocity model, T_c . Weighting of data has four components, (1) the analyst's subjective weight assignment at the time of phase data collection, which is based on the impulsiveness of the arrival, (2) the source-station distance, (3) the azimuthal quadrant which the source-station ray samples, and (4) the "feedback" residual weight. Weights assigned by the analyst are discussed further in YMP-USGS Technical Procedure SP-01, "Procedure for the preliminary determination of the earthquake hypocenter." We note here that an S-arrival weight at a given station is always downweighted relative to the corresponding P-arrival weight, since the S-wave slowness is greater and would increase its relative influence on the location process if such downweighting were not performed (see Gomberg and others, 1990, eq. 6). Distance weights, w_d , depend on the model. For all earthquakes that are located using the Yucca Mountain velocity model, shown in Appendix F, $w_d = 1$ for $d < 5$ km, and w_d linearly decreases with d in the range $5 \leq d \leq 90$ km. Station arrival time data for stations greater than 90 km from Yucca Mountain epicenters are automatically zero-weighted. For all other earthquakes in the SGB, $w_d = 1$ for $d < 10$ km, and w_d decreases linearly with d in the range $10 \leq d \leq 220$ km, and $w_d = 0$ for $d > 220$ km. Azimuthal weights attempt to balance the sum of arrival time data weights in each 90° quadrant, or in each 120° sector if station coverage is very poor. The azimuthal weight algorithm is discussed in greater detail in Lee and Lahr (1975).

The last weight factor is computed from each station's travel time residual, $(T_o - T_c)_i$. After each iteration after the second, the station residual is examined by the algorithm, and if its amplitude is relatively large, the i th weight is reduced, sometimes to zero. The computed travel time to each

station, T_c , is the minimum travel time for the direct ray and each of the possible refracted rays, for the given velocity model, plus any *a priori* delay that has been defined for the station.

Therefore, for a given set of arrival time data, there are infinitely many computable RMS functions, and the determination of the “quality” of a hypocenter is necessarily colored by the analyst’s choice of station delays, weighting functions, and velocity model (earth parametrization). For the hypocenters of this report, HYPO71 assigns two grades to the hypocenter (A through D, never F!), but neither grade fully accounts for uncertainties in the velocity model or in the station delays, or for the effects of information censoring performed by the weighting functions. The first grade focusses on the quality of the hypocenter (low RMS residual, small standard errors of the epicenter and depth), and the second on the station distribution (number of phases, station azimuthal gap, distance from source to nearest station). Lee and Lahr (1975) discuss HYPO71’s grading criteria in detail.

Where crustal velocities are not well known (for example, where velocities differ from the model velocities by more than 2 percent), primary and secondary wave arrival time data are usually insufficient to constrain the depth of focus estimate for local earthquakes to lie within approximately one standard-error-of-depth (as reported in Appendix A) of the true hypocenter (Gomberg and others, 1990). To some extent, this uncertainty is reduced by insuring that accurate P and S arrivals from a station within one focal depth epicentral distance are available - a condition which is absent for most data of this report, but which is driving the site selection for the upgrade seismic network, the deployment of which is presently under way. Although we routinely assign HYPO71’s depth of focus estimate, z , to earthquake hypocenters discussed in this report, the true depth should not be considered known to within one standard error of z unless “DMIN,” the source-to-nearest-station distance, is less than about $1.4 \times z$.

Estimated hypocenters for chemical explosions are reported in Appendix B. Many known chemical explosions are located treating depth a free parameter, and the results of some of those experiments are listed in Appendix B. If a blast’s depth is constrained during iteration for its epicenter, the depth is generally fixed at -1.0 (one km above sea level). The fact that unconstrained depth estimates for known blasts can exceed ten km below sea level is an indication of poor station coverage and of problems with the velocity model, especially in the source zone (SGB mining detonations often occur in low-velocity alluvium, with $V_p \leq 2$ km/sec, while $V_p = 3.8$ km/sec in the shallow layer of the standard SGB velocity model). The fact that earthquake data usually include several secondary wave arrivals that constrain the depth estimate whereas chemical explosion data usually lack such arrivals, as well as the probability that the earthquake source zone is better modelled by the simple layered velocity structure used in hypocenter determination than explosion source zones, imply that earthquake location accuracy is better than would be indicated by blast location errors reported in the chemical explosion catalog.

Alternatives to the forward-inverse approach to hypocenter determination have been suggested in various seismological research articles. A maximum-likelihood approach yielding a more comprehensive description of the hypocenter is explored by Gomberg and others (1990). In that approach, the inverse problem is avoided by computing *RMS* or an equivalent measure of goodness-of-fit at all points on a grid that surrounds the true source. The resulting hypocenter is then a “probability cloud” whose dimensions are determined by requirements of Gaussian distribution of the station travel time errors. In the interests of conciseness, that approach has not been adopted for data analysis in this report, although the variation of *RMS* with constrained depth is examined for a few hypocenters discussed below.

Can localized velocity anisotropy be inferred from NTS nuclear tests?

Whereas the comparison of true location with the estimated hypocenter of blasts (either chemical or nuclear device) provides, at best, indirect information about earthquake mislocation in a highly heterogeneous crust- unless they occur in the same place - the examination of station residuals

when using the true source location, and tracing rays using HYPO71 and the standard velocity model, provides useful, direct information about crustal rock velocities at shallow depths. This topic has been investigated for SGBSN P-wave arrival time data from several dozen nuclear device tests detonated at Pahute Mesa, Rainier Mesa, and Yucca Flat (manuscript in preparation). Although a complete description of the findings of this investigation is beyond the scope of this data report, some observations and speculations about their significance both to earth structure and to earthquake hypocenter determination are discussed below.

Arrival times of compressional waves at southern Great Basin seismic stations from nuclear device tests at NTS consistently display delay patterns with a strong directional signature or trend. Here, delay is defined as the difference between the observed arrival time and the theoretical time, when computed using the standard SGBSN velocity model, which is azimuthally isotropic. This apparent azimuthal anisotropy is observed to varying degrees in data from all testing regions, Yucca Flat, Rainier Mesa, and Pahute Mesa. Because seismic network station separation is on the order of 20-30 km, and the distribution of sources is limited, no detailed “tomographic analysis” of the upper crust is possible; however, the delay patterns are grossly related to known geology and to regional structural grain (orientation of microfractures, cracks, joints and faults), and to tectonic stresses.

Perhaps the most striking feature of the P-arrival delays for Rainier Mesa (southern Belted Range) nuclear device test data is their 180°-period azimuthal variation, which has peak-to-peak amplitude of one second, and appears to be nearly distance-independent for SGBSN station distances, ranging from 12 to 200 km. Figures 2a and 2b show the delays for Rainier Mesa tests Disko Elm and Mission Cybar, respectively, plotted as a function of azimuth. Figure 2c shows the “reduced” delays for the test detonation Disko Elm, plotted against source-to-station distance, where the 180°-period azimuthal effect, as defined in the next sentence, has been removed. Fitting the Disko Elm delays, T_i , with the function,

$$T_i(\theta) = a \cos^2(\theta_i - \theta_H) + b + \epsilon_i,$$

where θ_i is the source-station azimuth for the i th datum, θ_H is the “high-speed” azimuth, and ϵ_i is the unmodeled component of the i th delay (l^2 norm), yields $a = -0.741$, $b = -0.133$, and a correlation coefficient, ρ , of 0.80 between the data and the function values. The angle $\theta_H \approx 10^\circ$ maximizes ρ for the P-arrival data of Disko Elm, and lies in the range $10^\circ \leq \theta_H \leq 15^\circ$ for the other Rainier Mesa tests of Table 1. Furthermore, because P-delays show very weak distance dependence, it is reasonable to hypothesize that the azimuthal variations are generated in the inner 30 to 50 km of the source hypocenters (working points), or in a combination of the initial down-going and the final up-going portions of the raypaths.

Possible physical explanations for these anomalous travel time delays include the presence in the vicinity of Rainier Mesa of a high-speed body at shallow depth having longitudinal axis trending at $\approx \theta_H$, or stress-induced velocity anisotropy in much of the rock surrounding Rainier Mesa. The relevance of the stress-induced velocity anisotropy model (Nur, 1971) comes from the observation that θ_H is approximately perpendicular to the direction of average tension of SGBSN focal mechanism solutions, presented in previous SGB seismicity reports, and below, and to the direction of least compressive principal stress in the earth’s shallow crust, as determined from a series of Yucca Mountain hydrofrac experiments (Stock and others, 1985 and 1986). It is possible that P-wave velocities are being strongly influenced by aligned, propped open, cracks and microcracks in rock at shallow depths, according to the “extensive dilatancy anisotropy (EDA)” model (see Leary and others, 1990, for a review of recent seismological investigations on this topic). The possibility that seismic anisotropy results in significant P-wave velocity variations in the shallow crust of the southern Great Basin of Nevada is a current area of research.

If EDA is the primary source of the observed travel-time delay patterns from many NTS nuclear detonations, an 180° P-wave amplitude modulation effect (not necessarily sinusoidal) should also be observable in local station seismograms. This potentially diagnostic effect cannot be verified by

Figure 2.— Plot of P-wave travel time delays for NTS nuclear device tests recorded at SGBSN stations. Delays are relative to the predicted arrival times from the standard (azimuthally isotropic) velocity model shown in Figure F1(a). (a) For data from the Rainier Mesa test Disko Elm, open circles are observed delays plotted against source-to-station azimuth, closed triangles are values of $a \cos^2(\theta - 10^\circ) + b$, a sinusoid with 180° periodicity that attempts to fit the observed data. (b) Observed P-wave delays for the Rainier Mesa test Mission Cyber. (c) Disko Elm delays after removing $a \cos^2(\theta - 10^\circ) + b$ plotted against source-to-station distance. The lack of a linear trend in these residuals with distance suggests that the azimuthally varying component of the “signal” occurs near the source. (d) Observed delays (open circles) and a 180° period functional fit (dark triangles) for the P-wave arrivals for the Pahute Mesa test Alamo (880707 15:05:30 UTC), plotted against source-to-station azimuth. Note phase shift evident in (d) relative to (a) and (b). The larger average delay for Alamo arrivals relative to those of Rainier Mesa tests is the result of lower average compressional wave velocity in the shallow rock at Silent Canyon Caldera compared to that of other NTS testing areas.

the current SGBSN, since initial P-wave energy from most nuclear tests overdrives the telemetry electronics. Teleseismic P-wave amplitude modulations with period 180° have been observed from NTS explosions (Lay and others, 1984), but they were interpreted as radiation from strike slip tectonic release triggered by the tests. Although investigators are apt to model the propagation medium as isotropic, “one of the most powerful factors modifying radiation patterns of body waves in anisotropic media is focusing of energy near velocity maxima and defocusing near velocity minima. These effects are pronounced even for small anisotropy” (Tsvankin and Chesnokov, 1990, p. 11,330).

Large-scale heterogeneities in rock properties at NTS may also be the primary source of the strong variation in P-delay with azimuth. Measurements of some dolomite rock velocities from core samples taken from Rainier Mesa and northern Yucca Flat, NTS, indicate P-velocities approaching seven km/sec (Carroll and Magner, 1988). Much of the lower carbonate aquifer that extends through eastern and central NTS is comprised of dolomites and quartzites (Winograd and Thorardson, 1975). A ≥ 0.6 km thick dolomite section was encountered below a depth of 1.2 km at a borehole near Yucca Mountain, Nevada (Carr and others, 1986). The geographic extent of the lower carbonate aquifer is not precisely known. If it is terminated by the volcanic calderas of western NTS, and by an unknown relatively slow structure east of NTS, the lower carbonate aquifer may act as a high-speed corridor for seismic rays from Rainier Mesa and western Yucca Flat nuclear device source zones to many SGBSN stations that lie in sectors at azimuths $15^\circ \pm 15^\circ$ or $195^\circ \pm 15^\circ$ from those sources. The fact that the P-wave delays from sources at Pahute Mesa, for example, Alamo delays, plotted in Figure 2d, do not display the same high-speed phase angle, θ_H , as those from Rainier Mesa tests, suggests that (1), directions of horizontal principal stresses within Silent Canyon Caldera may be rotated 50° to 60° from those at Rainier Mesa, or (2), structural heterogeneity is the primary source of the azimuthal variations in travel-time delays.

Table 1. Summary of PDE location parameters for selected nuclear device tests at Rainier Mesa, 1985-1989, having strong azimuthal P-wave delay pattern. Dmin is the approximate epicentral distance to the nearest reporting SGBSN station, M_L is the Berkeley observatory magnitude.

DATE TIME (UTC)	LATITUDE, N.	LONGITUDE, W.	Depth (km)	Name	M_L	Dmin (km)

Contour maps of percent horizontal velocity variation from the underlying azimuthally isotropic model of Figure F1(a) are shown in Appendix C, figures C2, C3, and C4, for SGBSN station P-arrival delays computed for the NTS tests Alamo (a Silent Canyon Caldera test), Disko Elm, and Kawich (a Yucca Flat test), respectively. These contour maps show a similar high-speed corridor (the lower carbonate aquifer?) east of the caldera region of the western NTS, extending north and south of the NTS. The values of the velocity variation function, $\Delta V(x, y)$, are arrived at by the following reasoning. Let t_i be the i th source to station travel time (sec), Δ_i the source to station distance (km), v_i the i th apparent observed horizontal velocity, and u_i the i th apparent horizontal velocity computed by HYPO71 (u_i is a function of distance and station elevation). If we assume that the i th station residual computed by HYPO71, D_i , is the result of unmodeled horizontal velocity variations, then $t_i = \Delta_i/v_i = \Delta_i/u_i + D_i$, whence $u_i = \Delta_i v_i / (\Delta_i - D_i v_i)$. The percent velocity variation,

computed at the i th station's location, is then

$$\Delta V_i(\%) = 100 \times \frac{v_i - u_i}{u_i} = 100 \times \frac{-D_i}{t_i}.$$

$\Delta V(x, y)$ is then computed by interpolation/extrapolation of ΔV_i onto a (constant-elevation) grid over the SGB, and is plotted. Common features in the contour plots of data from different source regions (Figures C2, C3, and C4) suggest that crustal heterogeneity rather than azimuthal anisotropy may have a dominant role in the production of observed P-wave delays.

It is difficult to determine the extent of azimuthal velocity anisotropy at shallow to mid-crustal seismogenic depths because earthquake locations are uncertain, and typical hypocenter algorithms adjust available free parameters to reduce data/model misfit, thereby obscuring unmodeled properties of the earth. A theoretical study (Rothman and others, 1974) on the sensitivity of hypocenters to unmodeled transverse isotropy showed that epicenters will be consistently biased, regardless of assumed isotropic velocity used, and that depth estimate error varies linearly with fractional error in average velocity. Using actual SGBSN data, relocating Disko Elm as a hypothetical earthquake, allowing latitude, longitude, depth of focus, and origin time to readjust freely, HYPO71's final solution using the standard SGBSN velocity model converges to a depth about three km below sea level, indicating a low model velocity. The station residuals for the free hypocenter continue to show a faint azimuthal periodicity, but the correlation of delays with $T(\theta)$ drops to $\rho = 0.51$, from $\rho = 0.80$ when fixing the hypocenter at the true working point. It is easy to imagine that if the anisotropy imprint on arrival time data is not very clear to begin with, what signal there is will be lost by the typical hypocenter-determining algorithm which uses an azimuthally isotropic velocity model. However, routinely invoking an azimuthally anisotropic velocity model when determining hypocenters is not justified until alternate explanations (crustal heterogeneity) for the seismic travel time delays from NTS nuclear device tests have been fully discounted. One investigation having relevance to the question of how seismic anisotropy varies with crustal depth concludes that there is no evidence of shear-wave polarization at depths greater than three to five km (Kaneshima, 1990). Although that investigation analysed seismograms from events in the Japan volcanic arc, the underlying rock physics is similar for the SGB, and may imply that EDA effects may be confined to the final upgoing portions of most source-to-station raypaths for most SGB earthquakes.

Earthquake magnitudes and detection threshold

The SGBSN routinely detects earthquakes having $M_L \geq 1.5$ throughout the southern Great Basin. This size threshold drops to $M_L \approx 1.0$ in the southern NTS and to $M_L \approx 0.0$ at Yucca Mountain. For the SGB earthquake data listed in Appendix 1, 90% of the hypocenters have $M_L \leq 2.2$, and 95% have $M_L \leq 2.4$. Size estimation is done using one or more of the following methods, discussed in greater detail in YMP-USGS SP-04, "Preliminary determination of earthquake magnitude," (1), M_L from horizontal-component amplitude/period data, (2), M_L -equivalent from vertical-component amplitude/period data (vertical component amplitudes are multiplied by 1.75 to convert them to horizontal), (3), M_{ca} from fitting an envelope over the decaying S-coda in series of 5-second "windows" that do not contain overdriven amplitudes, (4), M_D from total coda duration, and (5), a M_L "lower bound" from clipped amplitude/period data. Measures (1) through (4) have been discussed in previous SGB data reports (Rogers and others, 1987). In previous reports, M_L was reported as the average of vertical-component and horizontal-component magnitude estimates; here, the two are reported separately. Figure 3 is a scattergram of the horizontal-component M_L estimates (scaled to the horizontal axis) versus the vertical-component estimates (scaled to the vertical axis) for about 800 randomly selected SGB earthquakes that occurred in the period 1987 through 1989. Least-squares regression of the y -values on the x -values for the data in Figure 3, constrained to pass through the origin,

$$y_i = ax_i + \epsilon_i,$$

1987-1989

Figure 3.- Comparison of horizontal-component instrument-determined local magnitudes, M_L^H , with vertical-component instrument-determined local magnitudes, M_L^V , for a subset of the 1987 through 1989 SGBSN hypocenter data.

yields a slope $a = 1.00$, indicating that the 1.75 factor that is routinely used to convert vertical amplitudes to “equivalent” horizontal amplitudes is reasonable for SGBSN data, in the sense that, on average, no bias is thereby introduced.

The fifth magnitude, M_L from clipped or overdriven data, is theoretically a lower bound on magnitude because the clipped amplitude is, by definition, less than the actual amplitude. However, in practice, this magnitude is not necessarily a lower bound when compared to other M_L estimates, because the clipped M_L is defined as the maximum of $M_L(j)$, where j is an index over all clipped, scaled, post-S wavelets, whereas the other M_L estimates are averages of all unclipped scaled data. Because the earthquake radiation pattern, site conditions, and other geologic variability all contribute to a large range in reported station magnitudes, we frequently observe that the averages of on-scale station magnitude estimates are lower than the maximum of the off-scale estimates. Magnitudes derived from clipped records are provided as a check on M_L computed from on-scale records. The seismic network upgrade will alleviate many of the problems associated with the current network’s high-gain, limited dynamic range design, including that of most stations’ amplifiers going off-scale for input signals from SGB earthquakes having $M_L > 3.0$.

We are often faced with the apparent paradox of reporting M_L from 38-dB horizontal-component station data that is on the order of one unit higher than M_L from 84-dB, vertical-component station data, for a given earthquake. Examples of this discrepancy are magnitudes for an earthquake on June 17, 1987, 0:00:50 UTC having $M_L^H = 4.18$ and $M_L^V = 2.8$ and an earthquake on October 28, 1988, 20:02:50 in Gold Flat (Mellan quadrangle) having $M_L^H = 3.40$ and $M_L^V = 2.78$ (the superscripts refer to horizontal-component and vertical-component, respectively). Tentatively, the primary reason for these discrepancies is that the network provides a severely biased sample of on-scale station data from earthquakes having $M_L > 3.0$. In other words, for larger microearthquakes in the SGB, an unbiased sample of the actual distribution of peak amplitudes of ground motion is not currently available; only those high-gain stations that sample the relatively low-amplitude tail of the distribution remain on-scale. Various calibration tests at the low-gain station at Little Skull Mountain and at high-gain stations run near the amplifier/VCO band edge have revealed no system non-linearity that might provide an alternate explanation. For a few earthquakes having $M_L \geq 3.5$, only low-gain horizontal-component station magnitudes are reported, since virtually all of the vertical-component station amplifiers are overdriven. Examples of such earthquakes are May 26, 1988, 03:56 UTC, for which $M_L^H = 4.2$, $M_L^{BRK} = 3.9$, and $M_L^{PAS} = 3.4$, in the Dry Mountain, California, quadrangle, and January 9, 1989, 05:08 UTC, for which $M_L^H = 3.5$, $M_L^{NEIC} = 3.5$, and $M_D^{RENO} = 3.6$, 10 miles north of Las Vegas, Nevada (Gass Peak SW quadrangle). The May 26, 1988 Dry Mountain magnitude discrepancy may be the result of only one SGBSN station, **LSMN**, providing an on-scale amplitude for magnitude determination, which is too few for a robust estimate. Also, **LSMN** generally provides a magnitude estimate several tenths above that of any other SGBSN station for a given earthquake, suggesting a local site amplification effect. If so, it is peculiar that the high-gain vertical component station, **LSM**, does not display a systematic magnitude bias relative to other vertical-component SGBSN stations.

The magnitude determination procedure for the SGBSN, in summary, is internally consistent for earthquakes having $M_L < 3.0$. For larger earthquakes, we have to rely on meager on-scale amplitude data from the SGBSN, which are difficult to calibrate due to the relative rarity of such events, or on estimates from adjoining seismic networks. For earthquakes having $M_L > 3.9^\pm$, the SGBSN has ≤ 1 on-scale station, and that station displays hints of overestimating magnitude by 0.3 – 0.5 units. Furthermore, the M_{ca} estimate has been calibrated against M_L for smaller earthquakes, having $M_L < 3$ (Rogers and others, 1987), but tends to underestimate larger earthquakes. Thus, the SGBSN magnitude estimates for earthquakes having $M_L \geq 3$ are preliminary and subject to revision as more data become available. For example, the upgrade seismic network, now being installed in the SGB, will have sufficient dynamic range to allow us to calibrate the current network’s horizontal-

component data against the upgrade network magnitudes.

Overview of local SGB seismicity, 1987 through 1989

In order to distinguish "local" seismicity from "regional" seismicity in this report, the southern Great Basin is defined as the interior of the region bounded by parallels 35.6° North and 38.5° North, and meridians 114.5° West and 118.0° West, respectively (definition 1). A more tectonically inspired definition would place the Sierra Nevada frontal fault as a western boundary, and the Garlock Fault as a southern boundary of the province (definition 2; see Carr, 1984); a few SGB earthquakes that are "regional" by definition 1 and local by definition 2 are discussed in this report. The SGBSN (Figure 1) does not extend to either the tectonic boundaries or to the above map boundaries, and no claims are advanced as to the completeness of the catalog outside the convex polyhedron with vertices at the outermost SGBSN stations. In particular, seismic activity in and southwest of the Panamint Mountains, California, is not routinely located, because the southern California seismic network covers that region. Also, north of 38.0° North, only one SGBSN station exists (HCR), and south of 36° North, only two SGBSN stations exist (QSM and EMN), not enough to constrain locations effectively in their vicinity. Station coverage east of the NTS, from Nellis Air Force Range to Alamo, Nevada, is also not sufficient to capture low-magnitude earthquakes in that area. With these limitations, the 1987 through 1989 catalog should be complete to a lower M_L bound of 1.5.

Data from "regional" earthquakes that are detected by the SGBSN's computer are permanently archived onto magnetic tapes, usually without analysis. These tapes include data from California earthquakes, including the seismically active Long Valley Caldera and the less-active southern Death Valley, from central Nevada earthquakes, and from earthquakes in eastern Nevada, western Utah, and northwestern Arizona. Regional earthquake data are available to and are frequently provided to seismologists investigating those regions.

SGB seismicity for 1987 is shown in Figure 4. Concentrations of southern Nevada earthquakes occur at the southern end of the Reveille Range, in the Pahroc Range, in the Pahranagat Shear Zone, in the Spotted Range (northwest of Indian Springs, Nevada), in the southern NTS (Rock Valley fault zone, Mercury Valley, Mine Mountain) in the central NTS (Eleana Range), in the northern NTS (Silent Canyon caldera), at Gold Flat, at Gold Mountain, Slate Ridge, and Mt. Dunfee, and in the Sylvania Mountains. A concentration of earthquakes near Mina, Nevada, occurred during July and August, 1987, with mainshock on July 28, at 18:55 UTC, having $M_L = 4.7$ (BRK), coordinates 38.383° North, 118.117° West, 14 km depth (not shown). Concentrations of California earthquakes occur in the Inyo Mountains, Eureka Valley, Last Chance Range, Grapevine Mountains, and in the Panamint Range. More diffuse activity occurs in Death Valley. All of these areas were active or moderately active in previous years (Rogers and others, 1987). Four earthquakes at Yucca Mountain, Nevada, are discussed in the next section.

SGB seismicity for 1988 is shown in Figure 5. The regions of concentrated seismicity for 1987 mentioned above continued to be active in 1988. Also, a second swarm area 10 km east of the first at the southern Reveille Range, Nevada, began to show activity in 1988. At Gold Flat, the seismicity level increased. A north-south trending concentration of microearthquakes in southwest Amargosa Desert, California, occurred in 1988 and 1989. Strongly felt earthquakes at Boulder City, Nevada, during the early part of 1988 (discussed below) prompted the installation of a permanent seismic station, EMN, in the Eldorado Mountains, south of Lake Mead, in August of 1988. Seismicity in the Eldorado Valley and in southern Lake Mead has been catalogued since that time by the SGBSN. The largest SGB earthquake for 1988 was a $M_L = 4.4$ earthquake in Owens Valley, California, on July 5, at 18:18 UTC. Although west of the SGBSN, the earthquake is within the physiographic province, and is of interest because a magnitude 7.5+, MMI=X, earthquake occurred in Owens Valley in 1872 (Beanland and Clark, 1987). A normal-slip focal mechanism for the 1988 Owens Valley earthquake is shown in Appendix D, Figure D23. At Yucca Mountain, an isolated earthquake occurred on October

Figure 4.— Earthquake epicenters in the SGB and SGBSN stations for the year 1987.

Figure 5.—Earthquake epicenters in the SGB and SGBSN stations for the year 1988.

5, 1988 and a small swarm of earthquakes occurred on November 18. Yucca Mountain seismicity is discussed in sections below.

SGB seismicity for 1989 is shown in Figure 6. Areas of concentrated seismicity for 1987 and 1988 continued to be active in 1989, although Yucca Mountain was seismically quiet. Sarcobatus Flat, noted for several seismicity swarms in previous years (Rogers and others, 1987), showed renewed activity in 1989, after being quiet in 1987 and 1988. Bare Mountain, Nevada, had several earthquakes in 1989. Yucca Flat, NTS, was seismically active, moreso than in the previous two years. Although the Oasis Valley, the western boundary of volcanic calderas that comprise most of the western NTS, was not particularly active in any one calendar year, it does show a north-south trend of epicenters for the 11-year monitoring period, 1979 through 1989. Figure 7 shows epicenters in the vicinity of the Oasis Valley for that period, along with the westernmost boundaries of major local volcanic caldera complexes (Christiansen and others, 1977; W. C. Carr, written communication, 1990). An earthquake on January 9, 1989, 10 miles north of Las Vegas, Nevada, was energetic enough to crack a few windows in Las Vegas, the only cultural damage reported to the NEIC from SGB earthquakes during the three-year period, 1987 to 1989. Its focal mechanism is discussed in a section below.

In an attempt to discern whether rates of seismicity are changing significantly with time in different parts of the SGB, we count the number of earthquakes recorded by the SGBSN in each of the $384 \frac{7}{2} \times \frac{7}{2}$ minute quadrangles contained in the region 114.875°W to 117.875°W , and 36.125°N to 38.125°N . (To increase legibility in the following figures, data for the outermost subregions of Figures 8 and 9, for example, those having longitude 117.875°W to 118°W , are not included in this compilation.) In each such quadrangle, two numbers are printed, the *top* being the number of earthquakes recorded in that quadrangle during the period 1987 through 1989, and the *bottom* being the number recorded during the previous three-year period, 1984 through 1986 (Harmsen and Rogers, 1987). A similar map shown in Figure 9 compares those same numbers of recorded earthquakes in 1987 through 1989 (*top* number) with those recorded in the period August, 1978 through December, 1983 (*bottom* number, Rogers and others, 1987). The two periods of seismic monitoring for which the data of Figure 8 are compared have the same station coverage, detection threshold, and instrumentation, whereas significant variations in station coverage, etc., occurred between the two periods compared in Figure 9. Therefore, caution needs to be exercised when comparing rates of observed seismicity in a given subregion. Also, significant spatial variation in detection threshold exists over the SGB, as noted earlier, so that comparisons of seismicity rates in different parts of the SGB should be made with caution.

Some of the most obvious temporal variations in seismicity rates for the data of Figure 8 occur at the Pahranagat Shear Zone, Nevada (roughly 37.25° North, 115.0° West), in the Reveille Range (roughly 37.8° North, 116.2° West), in the southern Montezuma Range (roughly 37.6° North, 117.4° West), at Gold Mountain (roughly 37.25° North, 117.25° West), at various locales within Sarcobatus Flat, in the Amargosa Desert south of NTS, and at Timber Mountain, which straddles the western NTS boundary (see figure 1 for locations of physiographic features). In these and other subregions, clear increases or decreases in rates are evident, suggesting that stable patterns of seismicity or aseismicity cannot necessarily be determined from a few years of seismic monitoring. This conclusion is reinforced by comparing the temporal variations evident when comparing the period 1987 through 1989 with 1978 through 1983. The Pahranagat Shear Zone was active during both of the periods, whereas the Reveille Range was seismically quiet during the earlier period. This quiescence is not the result of insufficient station coverage, as the SGBSN had a station, **RVE**, in the Reveille Range through July, 1981 (Rogers and others, 1987), which was then moved north to **HCR**, so that detection threshold in that subregion was comparable for all three periods.

While several zones having large temporal seismicity rate variations may be discerned, the majority of $7\frac{1}{2} \times 7\frac{1}{2}'$ quadrangles show relative rate stability. For example, within a 50-km radius of station **YMT4**, on Yucca Mountain (that station's location is shown in Figures 8 and 9), temporal

Alternate rows are shaded to aid in visual separation of information in adjacent quadrangles.

78-83 compared to 87-89

Figure 9.— Map of SGB region showing, on a $7\frac{1}{2}'$ quadrangle scale, the number of earthquakes recorded by the SGBSN in 1987 through 1989 (top number in each $7\frac{1}{2}'$ quadrangle) compared to number of earthquakes recorded by the SGBSN in the period, August, 1978 through December, 1983 (bottom number in each quadrangle). Alternate rows are shaded to aid in visual separation of information in adjacent quadrangles.

fluctuations in seismicity rates detected by the SGBSN appear to be relatively modest when comparing time periods of at least three years. These observations are purely statistical in nature. If the region surrounding Yucca Mountain, Nevada, indeed exhibits a more uniform rate of seismic energy release than many other subregions of the southern Great Basin, a physical mechanism should be found that explains this phenomenon. In particular, an improved understanding of zones where distortional strain is accumulating without displaying concomitant rates of microseismicity is needed to predict where future potentially hazardous earthquakes may occur.

Yucca Mountain seismicity, 1987 through 1989

The SGBSN operates six vertical-component S13 seismometers and two horizontal-component L4C seismometers at Yucca Mountain, so that microearthquake detection capability is at its maximum sensitivity there. Four small earthquakes were detected at Yucca Mountain in 1987, and of these, two were further analysed to obtain focal mechanisms (data quality was inadequate in the other cases). Eight earthquakes at Yucca Mountain were recorded in 1988, seven of which were members of a swarm having total duration 10 minutes; of these, one was large enough to provide a well-constrained focal mechanism. No Yucca Mountain earthquakes were recorded by the SGBSN in 1989. For the purpose of this categorization, Yucca Mountain is the interior of the region bounded by parallels at 36.75° N and 36.93° N, and meridians 116.375° W, and 116.56° W, respectively. This definition is somewhat arbitrary; the northwest end of Yucca Mountain blends topographically into the Timber Mountain Caldera, and the rest of Yucca Mountain rises from alluvial flats and washes. This region includes the Yucca Mountain area geologically mapped by Scott and Bonk (1984).

A Yucca Mountain velocity model, based on interpretations of Hoffmann and Mooney (1984), and shown in Appendix F, Figure F1(b), is input to HYPO71 for Yucca Mountain hypocenter determination. The effect of inputting the Yucca Mountain velocity versus inputting the standard SGB velocity model (shown in Figure F1(a)) on Yucca Mountain hypocenters is small. Figure 10(a) shows the effect that varying the assumed focal depth has on epicenter (left side) and on *RMS* (right side) when HYPO71 invokes the standard SGB velocity model for the Yucca Mountain earthquake of June 1, 1987 ($M_L = 0.1$). Figure 10(b) shows the same effects when the Yucca Mountain velocity model is invoked. For this arrival time data set, the minimum *RMS* occurs for hypocenters in the 5-6 km below sea level range, with $\min(RMS) = 0.04$ sec when using the standard model and $\min(RMS) = 0.08$ sec when using the Yucca Mountain model. The epicenters at a given depth derived from the two velocity models differ by about 0.2-0.3 km, which is a reasonable epicentral uncertainty estimate for Yucca Mountain earthquakes located using SGBSN station data, in agreement with HYPO71's standard error estimates. The fact that, in some cases, the Yucca Mountain velocity model fails to fit Yucca Mountain earthquake arrival time data better than the regional velocity model suggests that "fine-tuning" of the Yucca Mountain velocity model (for example, determining station corrections appropriate for that model and for local earthquake sources) may improve hypocenter estimates (or *RMS*). Table 2 summarizes Yucca Mountain earthquake location parameters for the period 1987 through 1989.

Table 2. Summary of preliminary location parameters for earthquakes located at or near Yucca Mountain, Nevada, for the years 1987 and 1988. "Distance to site" represents the epicentral distance to the point $36^{\circ}51'N.$, $116^{\circ}27.5'W.$, near the center of a potential national nuclear waste repository. Depth is relative to sea-level (0.0 km). Sdx, sdy, and sdz are HYPO71 standard errors in estimates of hypocentral longitude, latitude, and depth of focus, respectively.

Figure 10.—(a) *Left side*, the distribution of epicenters for various fixed-depth hypocenter solutions for the Yucca Mountain earthquake of June 1, 1987, 11:03:35 UTC, where all hypocenters are determined using the standard SGB velocity model (Appendix F, Figure F1(a)). The epicenter symbols are M, 0, 1, 2, ..., A, B, C, D, E, F, corresponding to depth-constrained hypocenters having $z = -1, 0, 1, 2, \dots, 10, 11, 12, 13, 14, 15$ km, respectively. The open square symbol at (0,0) is for a free-depth solution, with starting iterate depth 7 km, and the symbol “Z” is for a free-depth solution with starting iterate depth 0 km (at sea level). *Right side*, the variation in RMS travel time residual for various fixed-depth and free-depth hypocenters for that earthquake and velocity model. (b) The same distribution of epicenters (*left side*) and variation in RMS travel time residual (*right side*) as in Figure 10(a), except that here, the Yucca Mountain velocity model (Appendix F, Figure F1(b)) is used in hypocenter determinations.

Earthquake data gathered by the SGBSN to the present time indicates that Yucca Mountain is relatively inactive when compared to other nearby subregions, such as Rock Valley, southern NTS, Sarcobatus Flat, Oasis Valley, Timber Mountain, and parts of the Amargosa Desert. Bare Mountain is slightly more active, seismically, than Yucca Mountain. Crater Flat, separating those two mountains, is seismically quiet. A seismicity map of Yucca Mountain and the surrounding areas showing all catalogued earthquakes for the period 1979 through 1989 is shown in Figure 11.

Sometimes seismic hazard is estimated by considering the largest magnitude earthquake recorded in each subzone during a monitoring period. We present preliminary magnitude data to support this kind of analysis in Appendix A, Figure A5. In that figure a regional map, with Yucca Mountain at its center, shows the maximum earthquake magnitude (M_L where available, otherwise M_D or M_{ca}) recorded by the SGBSN in each $7\frac{1}{2}'$ quadrangle for two periods, (1) August, 1978 through December, 1986, and (2) 1987 through 1989. (Appendix A, Figure A5). (The location of station **YMT4** near Yucca Crest is shown in Figure A5.) No earthquakes having magnitude ≥ 1.0 have been detected in the quadrangle containing Yucca Crest, although magnitude 3.0^+ earthquakes have been monitored within 50 km of Yucca Crest at Silent Canyon Caldera and at Yucca Flat, NTS, in the Amargosa Desert, Nevada, and at Sarcobatus Flat, Nevada, during the monitoring period August, 1978, through December, 1989 (Figure A5).

1988 Boulder City, Nevada swarm

An extended swarm of small earthquakes occurred near Boulder City, Nevada, in 1988. The largest of the earthquakes felt in the Boulder City area were magnitude (M_L , USGS NEIC) 3.7, on February 23 00:48 UTC (February 22, George Washington's birthday, local time) and on July 4 10:56 UTC (Independence Day). Minor damage to some roof structures at Boulder City was locally reported following the February 23, 1988, earthquake, with epicenter in the Eldorado Valley (Boulder City News, July 7, 1988).

Historically, the Boulder City area has been seismically active since the construction of Hoover Dam and impoundment of Lake Mead in 1935-36 (Carder, 1970). The largest earthquakes (M_L 4.9 to 5.0) occurred between 1939 and 1963. Although there have been several temporary networks operated at Lake Mead over the years, no permanent network exists.

In order to better evaluate the significance of the 1988 swarm and its relation, if any, to seismicity induced by the impoundment of Lake Mead, a permanent station, **EMN**, was installed in the Eldorado Mountains south of Lake Mead on August 11, 1988, and a temporary network of portable seismographs was deployed around the Eldorado Valley and at southern Lake Mead during August and September. Preliminary results from the analysis of data from this network (M. Meremonte and C. Langer, written communication) show two areas of microearthquakes, one in the Eldorado

Figure 11.—Epicenters in the vicinity of Yucca Mountain, Nevada, for earthquakes recorded by the SGBSN in the 11-year period, 1979 through 1989. The small concentration of earthquakes in the northwestern part of Yucca Mountain occurred in November, 1988, with maximum magnitude 2.1. The concentration of seismicity at about 37° North latitude is within the southeast part of the Timber Mountain Caldera.

Valley south of Boulder City and the other northeast of Boulder City in the vicinity of Hoover Dam (see Figure 12). The earthquakes are relatively shallow ($z < 10$ km), and focal mechanisms are consistent with minimum stress (T axis) oriented between east-west and northwest-southeast, with maximum stress (P axis) ranging from north to northeast for the strike-slip mechanisms to vertical for the normal faulting events. These mechanisms are similar to those observed elsewhere in the SGB. Earthquake locations and focal mechanisms are also consistent with the observations of Rogers and Lee (1976) for the seismic network operated around Lake Mead during 1972-73, who proposed a physical model for impoundment-induced seismicity based on lower effective normal stresses on faults resulting from higher fluid pressure. If such a mechanism is still operating more than 50 years since the impoundment of Lake Mead, the recent seismicity may be a response to diffusion of water pressure into rock containing highly stressed faults. However, the pattern of occasional felt earthquakes followed by years of relative aseismicity in a locale is commonly observed in much of the Great Basin, and is not generally associated with reservoirs or with hydrologic cycles. In the vicinity of Lake Mead, stick-slip behavior may be operating much as it does elsewhere, but at lower stress levels. Expansion of the SGBSN into the Lake Mead region would provide an answer to the question of whether the vicinity of Lake Mead continues to be a region of elevated microearthquake activity.

Earthquake focal mechanisms

For the three year period 1987 through 1989, double-couple focal mechanisms obtained from thirty SGB earthquakes are discussed. Also, a previously unpublished focal mechanism for a Furnace Creek/north Tucki Mtn. (Panamint Range, California) earthquake that occurred on March 16, 1982, is included here. Most of the earthquakes are considered because of their relatively large size (maximum magnitude = 4.4); however, magnitude 0+ earthquakes at Yucca Mountain are analysed for their possible relevance to site characterization. For most of the focal mechanisms presented, the strike, dip, and rake of nodal planes are adequately constrained by P-wave polarities alone. For eight of the mechanisms, including those for three earthquakes at Yucca Mountain, first motions do not provide sufficient constraint, so vertical-component SV-to-P amplitude ratios, corrected for path and free-surface effects, are also used to constrain the range of focal mechanism solutions (Kisslinger and others, 1981 and 1982). The amplitude ratios and P-wave polarities are input into the computer program **focmec.for** (Snoke and others, 1984), along with instructions on how densely to sample the range of possible solutions, and how much data misfit to allow. The program outputs the set of solutions that satisfy the input criteria and data, and, if the range is sufficiently limited to be of practical use, the solutions are reported and plotted on an equal-area, lower hemisphere projection. The plotted subset always includes a solid-line solution (which may be unique, or, if not, has representative (average) strike and/or dip), and, optionally, one or two dashed-line solutions, which are shown to indicate the range of strike, dip, and/or rake angles that are consistent with the input data. The solid-line solution is designated as the primary solution, and the dashed-line solutions are designated as alternate solutions. Focal mechanism parameters are listed in Table 3, with indexes from 0 to 30, corresponding to the numbering in the epicenter/focal mechanism plot of Figure 13. To avoid crowding, Timber Mountain caldera focal mechanisms are plotted at the bottom of Figure 13. Individual focal mechanisms, showing the primary solutions of Table 3, and various alternates, are shown in Appendix D, Figures D1 through D37. The magnitude, M_L , that is reported for each earthquake is the average of the horizontal-component and vertical-component magnitudes, where each of those is the average of all on-scale horizontal-component magnitudes and vertical-component magnitudes, respectively, scaled at SGBSN stations, unless otherwise noted. "DMIN" is the minimum source to station distance. (Hypocenter parameters reported in Appendix D may not correspond exactly to those reported in Appendix A. Appendix D hypocenters often are the product of a more careful analysis of seismic wave arrival times, residuals, and polarities, than the routine data analysis that results in Appendix A hypocenters. All reported hypocenters and

Table 3. Preliminary Southern Great Basin Focal Mechanisms 1982 and 1987-1989.

St, *strike of nodal plane*; **Dp**, *dip of nodal plane*; **Rk**, *rake of slip vector*; **Tr**, *trend of axis*; **Pl**, *plunge of axis*; **ML**, *local (SGB) magnitude*; **Tsm**, *type of source mechanism*: 1, *single event focal mechanism*; 2, *composite focal mechanism*. Nodal planes: No inferred fault planes for these focal mechanisms are presented here, although for many of the mechanisms, inferences about the preferred nodal plane based on lineations of epicenters and/or on the state of tectonic crustal stress are possible. For example, if the maximum horizontal compressional stress is oriented at about North 20° to 30° East, then right-lateral strike slip may be expected on steeply dipping, north-trending fault planes with greater likelihood than left-lateral strike slip on east-trending fault planes, other mechanical conditions being equal. Rmk: Remarks, designated by *, means that (SV/P_z) amplitude ratios were used to constrain or help determine the focal mechanism. Alternate focal mechanisms: rather than trying to present uncertainty estimates for strike, dip, and rake, we present alternate solutions as dashed-line great circles. Other alternate primary and secondary solutions for different hypocenters are shown in Appendix D. Solutions based on fixed-depth hypocenters are indicated by a * next to the focal depth.

Figure 13.— Regional map of SGB showing lower-hemisphere projections of earthquake focal mechanisms indexed to Table 3. Event 0 occurred in 1982, all others (1-30) occurred in the period 1987 through 1989. The focal mechanisms are plotted near the earthquake epicenters, for all events except those at Timber Mountain (events 8, 19, and 26), which are plotted at the bottom of the map. Two mechanisms are included for event 10, to show how different interpretations are possible for the same earthquake first motion data, resulting from different assumed depths of focus.

focal mechanism solutions are preliminary.)

Effects of modeling on focal mechanisms

The SGBSN has very sparse station coverage away from Yucca Mountain, with average station spacing of 20 to 30 km. The main consequence of the limited station coverage is poor resolution of most earthquakes' depth-of-focus, when using the standard velocity model and first-arriving P and S waves to determine the hypocenter. For example, many earthquake arrival time data sets display nearly equal local RMS travel time residual minima for $z \approx 2$ km below sea level and $z \approx 7$ km below sea level. The effect of varying depth-of-focus on the earthquake focal mechanism is explicitly examined for many of the data presented here. When deriving focal mechanisms from various hypocenter solutions, we invoke the same velocity model for ray tracing; therefore, the observed variations in mechanism for a given earthquake are a consequence only of ray parameters varying due to different source depths and not to different velocity models. In some instances, the P-wave polarity data help to prescribe which velocity model is used in hypocenter determination (a good example is shown in Appendix D, Figure D20; also, see the following paragraph). It should be noted that changing the velocity model may change the solution set of focal mechanisms, even if the hypocenter remains the same. For example, ray tracing from a crustal model in which seismic velocities increase linearly with depth may yield different focal mechanisms than those from data derived from models in which seismic velocities are fixed within a series of layers with velocity discontinuities at the interfaces, as we presently use in preliminary hypocenter determination for SGB earthquakes. This report does not systematically investigate the effect on focal mechanism parameters of changing the seismic velocity model.

Experience computing earthquake focal mechanisms from SGBSN data indicates that adding an interface (sometimes referred to as the Conrad discontinuity) somewhere between 12 and 15 km below sea level, below which $V_p = 6.5$ km/sec, often improves the fit of P-wave polarity data to focal mechanism nodal plane solutions. This interface has been used for determining hypocenters and raypaths for many of the earthquakes for which focal mechanisms are presented in this report. Examples of focal mechanisms which require this interface are shown in Appendix D, Figures D4, D14, and D20.

In previous SGBSN data reports, the 15 km interface is absent, although another interface, located 24 km below sea level, below which $V_p = 6.9$ km/sec, is present in all reports, and may also be identified as the Conrad discontinuity. *RMS* for the vast majority of SGB earthquake hypocenters is not significantly affected by the presence/absence of the 15 km interface, and therefore cannot be invoked to justify its inclusion/exclusion. For a very small subclass of hypocenters, namely, those having depths near the 15 km interface, *RMS* is sensitive to its presence/absence; an example is discussed in the section entitled "depth-of-focus distribution and deep-crust intraplate earthquakes."

Whereas the *RMS* travel time residual from local earthquake data is not a very sensitive tool for ascertaining the presence of mid-crustal to deep-crustal layer interfaces, the earthquake focal mechanism often is, as long as we consider only those mechanisms that arise from pure shear deformation. Unless an active magmatic process or other high-fluid-pressure phenomenon is present, there is probably no compelling reason to doubt that the microearthquake source can be represented by a double-couple. Thus, this report takes the position that if quadrantal partitioning of unambiguous P-wave polarity data from SGB microearthquakes requires the modification of the velocity model, and if such modification does not degrade *RMS*, and does not contradict established models, then it is more scientifically justifiable to modify the velocity model than to argue that the polarity data imply other than pure shear source properties.

Independent confirmation of the presence of a strong P-wave velocity gradient or a velocity discontinuity at some depth between 12 and 15 km below sea level would be helpful. Seismic refraction is the natural tool for searching for such a discontinuity. Pakiser's review (1985) of papers written in the previous three decades that deal with interpretations of seismic refraction

data in the Basin and Range province suggests that refraction seismologists have divided opinions on the visibility of P^* phase(s) that should arrive from such mid-crustal reflectors, both province-wide, and more specifically, at NTS. Hoffman and Mooney (1984) observe evidence for a 15 km interface in an east-west profile across Yucca Mountain, but not in an unreversed profile from a nuclear device detonation at Pahute Mesa. Ismail and Priestley (1986) also argue that a mid-crustal layer boundary (12 to 16 km) is present in the vicinity of Yucca Mountain, Nevada, based on their interpretations of P-arrivals from east-west and north-south profiles. Serpa and others (1988) note "a prominent zone of reflections at a traveltimes of 5 ± 1.5 sec (15 km)" in the central Death Valley and surrounding mountain ranges (p. 1446), which they interpret as either a deep detachment, a zone of transition between the brittle upper crustal rocks and a ductile lower crust, or as an uplifted rock horizon originally formed at the base of the crust. In a recent interpretation of combined refraction, reflection, and gravity data in northwest to central Nevada (about 4° north of the SGB), Catchings and Mooney (1991) found mid-crustal reflectors at depths ranging from 12 to 18 km, below which $V_p = 6.3$ km/sec. These reflectors, which they interpreted as a possible brittle-ductile transition zone boundary, extended over the length of their survey, 200 to 300 km. In summary, available evidence appears to either support or not reject the existence of mid-crustal reflector(s) in the SGB.

Representativeness of focal mechanisms in the SGB catalog

Because the focal mechanism solutions presented in Appendix D of this report include data from only about one percent of the local earthquakes located and catalogued in the period 1987 through 1989, it is difficult to argue that they represent an unbiased and adequate sample of earthquake sources sufficient to characterize seismic deformation of shallow crust in the SGB. However, insofar as polarities can be determined for P-arrivals of smaller earthquakes for which focal mechanisms were not computed, there is a remarkable consistency of azimuthal partitioning of polarities for the vast majority of SGB earthquakes. For most earthquake source regions in the SGB, first motions of P rays travelling from the source into the northwest and southeast quadrants are compressional. First motions of P rays travelling in the interior of the northeast and southwest quadrants are usually dilatational. Near the edges of these quadrants, the first motions may be compressional or dilatational, depending on whether the seismic slip is predominantly normal or strike slip, respectively. A significant counterclockwise rotation of this first motion pattern is observed for many earthquakes in the westernmost part of the southern Great Basin, as is evident from several focal mechanisms presented in Appendix D, the most pronounced case being for the Owens Valley earthquake of July 5, 1988 (Figure D23). The rotation of the average strain field from the center of the SGB to its western boundary is further discussed in Rogers and others (1989) and below, in the section "average directions of \vec{P} and \vec{T} and tectonic strain."

The bulk of SGB earthquake P-arrival data, whether from earthquakes having well-constrained focal mechanisms, or from smaller earthquakes, tend to support the model of earthquake generation from uniform regional stresses and deformation processes more than it supports the model of microearthquakes being a nearly chaotic accommodation to local perturbations of the stress field. Conceptual models of the strain field in the shallow to mid-crustal rock of the SGB should account for the consistent patterns of P-wave first motions that are generally observed by the SGBSN for most SGB earthquakes.

Untypical focal mechanisms and source zones in the SGB

While the azimuthal distribution of P-wave first motions discussed above is likely to be observed for most SGB shallow-crustal to mid-crustal earthquakes, a few earthquake data sets do not conform to that pattern. An example of a data set having first motions that are 180° out of phase from the norm is that of an earthquake on May 30, 1985, at northern NTS (Tippipah Spring quadrangle), shown in Figure 13 of Harmsen and Rogers (1987). Two focal mechanisms from earthquakes in the

epicentral vicinity of that May, 1985, earthquake, which occurred in July, 1984, also reported in Harmsen and Rogers (1987), display typical P-wave azimuthal distributions.

For sources within the Silent Canyon Caldera, in the vicinity of Pahute Mesa underground nuclear explosions (UNEs), earthquake seismograms from SGBSN stations often exhibit either dilatational or indeterminate first motions, even in the northwest and southeast quadrants of the focal hemisphere, indicating the possibility that these initiate predominantly as isotropic, volume-reducing events rather than as double-couple events. Because of the sparsity of U.S.G.S. seismic station coverage in the vicinity of the Silent Canyon Caldera, the proportion, $r : 0 < r \leq 1$, of deformation at the seismic source that is deviatoric (double-couple) rather than isotropic (spherical) cannot be determined using P-wave polarity information only; if we assume $r = 1$, the mechanisms exhibit approximate 90° rotation of pressure and tension axes from the regional averages. Two examples of double-couple interpretations for these peculiar Silent Canyon Caldera events are included in Appendix D, Figures D21 and D31. Another good example of a SCC earthquake having almost exclusively dilatational first motions is that of September 26, 1987, 22:52:31, listed in Appendix A, which occurred about 56 hours after the relatively large UNE, Lockney ($M_b = 5.7$). A possible explanation of such events at SCC is that they are seismic release from the closing of tension cracks formed during nuclear device tests, or from partial implosion of the cavity. If this is the case, it is probably true that $r \ll 1$ for these SCC events, in which case the double-couple interpretations are invalid.

Yet another class of events following UNEs (which probably overlaps the class of "dilatational sources" discussed above) is that of the "low-frequency events." Seismogram dominant frequencies for both P-coda and S-coda are significantly lower for these events than those observed in "natural" earthquake seismograms at comparable source-to-station distances. The remarks about typical distributions of P-wave first motions and focal mechanism properties therefore do not apply to the events that are most closely associated, both temporally and spatially, with UNEs. Such post-test phenomena are probably induced by the tests, and need to be separated both from the earthquake hypocenter catalog when we estimate rates of regional natural seismic strain, and from the focal mechanism catalog, when we compute the average direction of extension or other strain parameters. Most hypocenters of events during the period 1987 through 1989 having coda with lower-than-average frequency content, whether in the Silent Canyon caldera or elsewhere in the SGB, have been separately tagged and listed in Appendix C of this report. In general, because of the large number of such phenomena, and the noisy, emergent nature of first motions at many stations, no attempt is made to routinely determine hypocenters for the vast majority of these low-frequency events. However, their seismograms are all archived onto magnetic tapes to provide a permanent data base for future research. Of the three NTS nuclear device testing regions, Pahute Mesa, Rainier Mesa, and Yucca Flat, the most active region with respect to quantity of potentially induced seismicity per test of a given reported magnitude is Pahute Mesa, and the least-active region is Rainier Mesa.

Inasmuch as low-coda-frequency events have been occasionally recorded in the SGB away from the NTS, we cannot rule out the possibility that some are not induced by nuclear device tests. One class of low-coda-frequency seismicity that is definitely natural is that of relatively deep-focus earthquakes, at the crust-mantle interface, examples of which are discussed in the section, "depth-of-focus distribution and deep-crust intraplate earthquakes." If the event's hypocenter and origin time strongly suggest that it is not induced by cultural activity, it is included in the earthquake catalog and listed in Appendix A, regardless of the frequency content of SGBSN seismograms.

Evidence of seismically active detachment faults?

The possibility that detachment faults are seismically active in parts of the SGB has not been previously documented to the authors' knowledge. Much of the large-scale extensional tectonics of the southern Great Basin during the Neogene period is now understood to require a major component of block movement along gently dipping faults (Wernicke and others, 1988). Therefore, it should

not be surprising if some of that movement is sufficiently “catastrophic” to result in earthquakes detectable by the SGBSN. However, under Hamilton’s (1988) model for detachment faulting in the Death Valley region, detachment faults would originate as moderately-dipping or steeply-dipping normal fault segments. Fault dips become more gentle through unloading and ductile deformation of the lower plate, and fault segments may be inactivated as their dip becomes too gentle to permit further slip. Such fault segments would not be expected to be seismogenic.

All double-couple focal mechanisms have two orthogonal nodal planes. If the inclination or dip of one of those planes is $\approx 20^\circ$ or less, that focal mechanism solution provides evidence of a possible seismically active detachment fault. Without further geological or geophysical information about deformation in the vicinity of that hypocenter, detachment is one of two possible interpretations, and not the most likely unless movement on the near-vertical auxiliary plane can be discounted. No instances are given in this report where we wish to imply that the probability of slip on the near-vertical auxiliary plane is significantly less than 0.5. However, in addition to the major, if not dominant, role that shallow-dipping faults must play in the large-scale Neogene extension of the southern Great Basin, shallow-dipping nodal planes of focal mechanisms are sometimes unavoidably present in SGBSN data sets. If these shallow dipping nodal planes are not the fault planes, we are left with vertical slip on very steeply-dipping faults, implied by the auxiliary nodal plane of such focal mechanisms. Such deformation yields almost no net crustal extension, and provides as many obstacles to plausibility from a rock-mechanics perspective as does seismic slip on gently dipping faults.

The first example of a shallow-dipping nodal plane for the focal mechanism solutions computed for this report is for an earthquake of April 20, 1987, in the Specter Range SW quadrangle (Appendix D, Figures D5 and D6). This shallow-dipping nodal plane is somewhat “robust,” in the sense that, for two very different assumed hypocenters, the dip of the plane remains sub-horizontal, although the angle of slip changes from -90° (normal slip) for the surface focus hypocenter, to 0° (strike slip) for the six km below sea level hypocenter. Several focal mechanisms presented in this report have primary or alternate solutions with a nodal plane whose dip is less than 20° (Appendix D, Figures D7, D11, D17, D19, D20, D33, and D34). For some station geometries relative to SGB sources, the shallow dipping nodal plane “goes away” by changing the assumed hypocentral depth (compare Figures D18 and D19, for example). Other cases in which the focal mechanism primary solution contains a nodal plane whose dip is strongly dependent on the assumed hypocenter depth are discussed below. These observations are intended to emphasize that for the current SGBSN and probably for many regional seismographic networks, uncertainties in source properties inferred from their focal mechanism solutions are frequently substantial.

One possibly important example of a focal mechanism having a shallow-dipping nodal plane that does not “go away” by depth-of-focus manipulation is that for an earthquake in the Grapevine Mountains, California (Dry Mountain quadrangle), on May 26, 1988, 03:56:49 UTC. This earthquake is among the largest of SGB earthquakes recorded by the SGBSN in 1988. Because of its magnitude, this earthquake’s P-wave polarities are exceptionally clear. The quadrantal distribution of first-motion P-polarities for SGBSN data *does not occur* for assumed hypocenters less than about 6-7 km below sea level, i.e., for shallower focus hypocenters, dilatations are hopelessly intermixed with compressions when plotted on the lower (equivalently, upper) hemisphere around the assumed source. The distribution of first motions does partition into quadrants of like polarity without significant inconsistencies for a source with assumed 7 km depth (Appendix D, figure D20), when source-to-station rays are computed using the velocity model of Appendix F, containing a velocity discontinuity at 15 km. Supplementary data from the southern California and central California seismic networks (PAS and MNLO, respectively) were included to help constrain the focal mechanism, which has a nodal plane dipping 21° . Slip is normal. This example may be among the strongest evidence yet collected by the SGBSN for possible seismic slip on a shallow-dipping surface. However, this

plane, if the fault plane, is perhaps too steeply dipping to imply seismic activity on a detachment surface. Other examples presented in this report have more shallow-dipping nodal planes, but these are generally less well-constrained than the May 26, 1988 earthquake's focal mechanism.

Yucca Mountain earthquake focal mechanisms

Three earthquakes at Yucca Mountain are examined to see if it is possible to derive focal mechanisms; a magnitude 0.4 on March 10, 1987, a magnitude 0.1 on June 1, 1987, and a magnitude 2.1 on November 18, 1988. For each of these, hypocenters were relocated using a flat layer velocity model having P-wave velocities and layer interfaces that approximately correspond to those found by Hoffman and Mooney (1984) in a refraction survey of Yucca Mountain. These velocities are lower near-surface than those of the standard SGB model, with the consequence that seismic rays traveling to Yucca Mountain stations suffer more refraction towards the vertical than in standard model paths. The two models' P and S velocities are plotted as a function of crustal depth in Appendix F, Figure F1. Because none of the Yucca Mountain earthquakes was large enough to be adequately constrained by P-wave first motions, SV and P vertical ground vibration amplitude data were gathered, and had to be corrected for propagation effects to provide SV-to-P amplitude ratios representative of the source only. These path corrections are dependent on the earthquake's depth-of-focus, with greater amplitude corrections necessary for deeper focus hypocenters. The Yucca Mountain velocity model differs from the "standard" SGB velocity model in the important detail that all source-to-station rays from SGB crustal earthquakes arriving at Yucca Mountain stations are incoming at $\phi < \phi_c$, where ϕ is the free-surface angle of incidence, and ϕ_c is the critical angle. When ray tracing is performed using the standard SGB velocity model the opposite case is true, $\phi > \phi_c$. Although this modeling consideration may appear to be of only academic interest, the use of slow surface-layer velocities results in different focal mechanism interpretations for the extremely small Yucca Mountain earthquakes than would result when using the standard SGB crustal model for ray tracing and propagation effect corrections.

The largest recorded Yucca Mountain earthquake ($M_L = 2.1$) from the inception of the SGBSN in 1978-1979 through 1989 occurred on November 18, 1988, 20:32:24 UTC, at 36.925° North latitude, 116.553° West longitude, and 11 km below sea level depth. The epicenter is about 12 km northwest of the site of a potential national high-level nuclear waste repository (shown in Figure 11). Focal mechanism solutions for this earthquake are not sufficiently well constrained from SGBSN P-wave first motion polarities; thus, $(SV/P)_z$ amplitude ratios are used to limit the range of solutions. Seismic energy of the S-coda of the mainshock overdrove the telemetry electronics of all Yucca Mountain stations. Yucca Mountain station seismograms from a small foreshock, which preceded the mainshock by a minute, were scaled to provide amplitude and period data for $(SV/P)_z$ ratios (this procedure assumes that the hypocenters *and* elastic energy radiation patterns of the two earthquakes are nearly identical). Path corrections having amplitudes several times those of the $(SV/P)_z$ ratios were added to remove propagation and free-surface effects (these corrections are sensitive to assumed incident angle of P and S waves at the free surface, thus to velocity model). If we accept the validity of these modelling assumptions, the resulting focal mechanism solutions are well-constrained. The azimuth of T is $276 \pm 3^\circ$, its plunge is $18 \pm 5^\circ$; the azimuth of P is $178 \pm 3^\circ$, its plunge is $28 \pm 9^\circ$. All solutions are predominantly strike slip, with some alternate solutions having a component of reverse slip. Two representative solutions are shown in Appendix D, Figure D28, with the "observed" and theoretical $(SV/P)_z$ ratio data for each solution. The tension axes for these solutions trend west, and are therefore rotated counterclockwise from the average direction of T for SGB focal mechanisms (see the section, "average directions of \vec{P} and \vec{T} and tectonic strain" below). The southwest-trending nodal plane of the primary solution, if imagined to project to the earth's surface as a planar fault, would crop out $3\frac{1}{2}$ km southeast of the hypocenter, or 8 km northwest of the potential repository's location on the crest of Yucca Mountain. Slip on that plane is oblique left-lateral strike slip with a substantial normal component. No Quaternary faults or lineaments have been mapped in the

vicinity of that plane's surface projection (Reheis and Noller, 1990). The northwest-trending nodal plane has predominantly right-lateral strike-slip motion. If projected to the surface, it would crop out at Bare Mountain, cutting the trace of the Bare Mountain fault.

Selection of the fault plane for this Yucca Mountain earthquake from the two (solid-line) nodal planes of Figure D28 is possible based on plausibility arguments taken from rock physics. If the direction of minimum horizontal compressive stress in the vicinity of the hypocenter of November 18, 1988, is approximately the same as that inferred by Stock and others (1985 and 1986) from hydraulic fracturing measurements at various Yucca Mountain drillholes, $\text{azi}(\sigma_3) = \text{N}60^\circ - 65^\circ\text{W}$, then application of the Coulomb-Mohr failure criterion to the two nodal planes of the primary solution of Figure D28 selects the northeast-southwest trending plane as the fault plane. In other words, when considering the ratio of applied shear stress, τ_{xy} , to effective normal stress, σ_n , on each nodal plane, the condition

$$|\tau_{xy}| \geq 0.7\sigma_n$$

occurs when the fault normal direction, $\vec{n} = \vec{Y}$, where \vec{Y} is the normal to the northeast-southwest trending nodal plane, but not when $\vec{n} = \vec{X}$, where \vec{X} is the normal to the other nodal plane (see Figure D28). Here, in order to satisfy the Coulomb-Mohr criterion using a plausible friction coefficient, $\mu = 0.7$, it is assumed that the ratio of effective maximum principal compressive stress, to effective minimum principal compressive stress, $\frac{\sigma_1 - P_p}{\sigma_3 - P_p}$, is approximately four in the vicinity of the hypocenter. P_p is the local fluid pore pressure. To satisfy another plausibility criterion, that the direction of slip on the fault plane equals the direction of maximum shear stress on that plane, the amplitude of the intermediate principal compressive stress, σ_2 , is considered a free parameter (in the range $\sigma_3 < \sigma_2 < \sigma_1$). This Coulomb-Mohr analysis also suggests that σ_1 is oriented subhorizontally at the hypocenter, a conclusion that would also be valid if the alternate (dashed-line) nodal planes of Figure D28 had been considered. (Harmsen and Rogers (1986) discuss this process of fault plane selection from rock physics considerations in greater detail.) The dip of the inferred fault plane of the primary solution, 74° , is probably too great for that plane to correspond to Quaternary faults on Yucca Mountain having similar trend, mapped by Scott and Bonk (1984), who state that faults at Yucca Mountain that dip approximately 70° at the surface and display a "major dip slip displacement" tend to flatten somewhat with depth, with 60° dip at depth $>$ one km.

The other two focal mechanisms for Yucca Mountain earthquakes occurring in 1987 were for earthquakes that, anywhere else in the SGB, would have been considered far too small to investigate ($M_L = 0.4$ on March 10, 1987, and $M_L = 0.1$ on June 1, 1987). The March 10 earthquake, with a focal depth of 3.1 km below sea level, has a well-constrained focal mechanism from six polarities and four ratios, if we require a very close fit between all theoretical and "observed" ratios (maximum difference between logarithms = 0.15). The resulting mechanism is predominantly strike slip, with substantial normal component, on either a north-northwest trending nodal plane or on a west-southwest trending nodal plane. The north-northwest striking nodal plane dips east at about 66° , and the west-southwest striking nodal plane dips northwest at about 55° . Mapped Quaternary faults in the vicinity of the epicenter, such as the Solitario Canyon fault and the Windy Wash fault, trend north, with gentle undulations. Most of the mapped faults on the west side of Yucca Mountain dip to the west, perhaps forming a headwall complex for the Bare Mountain detachment fault, most active 12.5 million years BP (Scott and Whitney, 1987). Because of its dip, the focal mechanism's north-south nodal plane does not appear to be related to remanent activity of that system. The auxiliary nodal plane's strike does not correspond to any mapped fault orientations in the vicinity of the epicenter. The orientation of the tension axis, with azimuth $\text{N}68^\circ\text{W}$, approximately coincides with the direction of inferred minimum horizontal compressive stress at Yucca Mountain (Stock and others, 1985 and 1986). Because constraint on the range of focal mechanism solutions is achieved by closely fitting four $(SV/P)_z$ amplitude ratios (implying that many assumptions about the earth model are valid for this data set), our confidence in these focal mechanism parameters is relatively

"low."

The set of plausible focal mechanisms for the $M_L = 0.1$ earthquake of June 1, 1987, with depth of 5.9 km below sea level, is not well constrained even when four amplitude ratio data supplement the five unambiguous P-wave polarities. A strike-slip focal mechanism solution, shown in Appendix D, Figure D7, has only marginally better amplitude ratio fit than an alternate normal-slip mechanism (RMS ratio error = 0.180 versus 0.197) when all "observed" ratios are required to have amplitudes within a factor of two of theoretical values. One of the nodal planes of the normal-slip mechanism dips about 10 degrees to the east, which, if the fault plane, is an example of a possible active detachment fault at Yucca Mountain. If the strike-slip solution is correct, the north-northwest trending nodal plane agrees in strike and dip with the Solitario Canyon fault, but not with mapped sense of slip. The T-axis for the strike slip solution also trends parallel to the direction of minimum horizontal compressive stress as determined from hydrofrac measurements at Yucca Mountain drillholes (Stock and others, 1985 and 1986).

In summary, focal mechanism solutions for Yucca Mountain, Nevada, earthquakes detected through 1989 are poorly to, at best, moderately well constrained when only P-wave polarities are used in their determination. This lack of constraint is the direct result of the inability of most SGBSN sensors to detect first motions, due to the very small size of Yucca Mountain earthquakes recorded through 1989. While supplementing polarity data with $(SV/P)_z$ amplitude ratios is sometimes, but not always, able to constrain the solution set to a narrow, geologically plausible, range, the ratio method borrows heavily on hard-to-validate assumptions. A better understanding of seismic slip at Yucca Mountain and vicinity requires that we improve seismographic coverage there, a project that is currently underway by YMP-USGS.

While we have attempted to relate the microseismicity at Yucca Mountain to relatively major mapped Quaternary faults there, it is probable that much of the SGBSN's monitoring is recording activity on secondary structures, such as Riedel shears; thus, correlation of focal mechanism parameters with major faults may be expected to be low. A second caveat may be in order. The shallow (≤ 1.5 km below surface) hydrofrac determinations of minimum compressive stress that were invoked to determine the fault plane for the Yucca Mountain earthquake of November 18, 1988 (Appendix D, figure D28) may not be appropriate for seismogenic depths. Such factors as topographic influence on the crustal stress field (Swolfs and others, 1988) or a detachment surface may not justify extrapolation of those hydrofrac measurements to depths corresponding to earthquake hypocenters considered in this section.

Reverse-slip focal mechanisms and compressional tectonism in the SGB

Tucki Mountain and the Panamint Range, California, may have moved $\approx 125 \pm 7$ km in the direction $N65 \pm 7^\circ W$ from the Nopah block during the Neogene period (Wernicke and others, 1988), and may therefore be expected to display significant seismicity if this extensional process is still active. Prominent reverse-slip faults have been observed at Tucki Mountain (Wernicke and others, 1988). The mainshock of a short-lived Tucki Mountain series of earthquakes in March, 1982, reported in Rogers and others (1987), provides sufficient P-wave polarity data from the SGBSN and from the southern California seismic network (PAS) to yield a well-constrained focal mechanism (Appendix D, Figure D1). The focal mechanism of the earthquake ($M_L^{PAS} = 3.4$) has east-west trending and northwest-southeast trending nodal planes, each with oblique reverse slip. The mainshock's epicenter is at the northernmost end of Tucki Mountain (Panamint Range), about 25 km northwest of the northern end of the north-trending, right-lateral strike-slip Death Valley fault, and about 12 km southwest of the northwest-trending right-lateral Furnace Creek fault zone.

Although well-constrained oblique-reverse-slip focal mechanisms are extremely uncommon in the southern Great Basin, "most 'strike-skip' faults ... are associated with an assemblage of related structures including both normal and reverse faults" (Christie-Blick and Biddle, 1985, p. 1). The

deformation implied by the March, 1982, Tucki Mountain mainshock may be the result of compressional strain west of the junction of the Death Valley and Furnace Creek fault zones in the manner predicted by laboratory-scale photoelastic models of segmented faults (see Freund, 1974, his figure 27).

Compressional tectonism is of some interest to site characterization, because of its potential to interact with the hydrologic subsystem. No unequivocal, predominantly reverse-slip focal mechanism solutions have been determined from SGBSN data for earthquakes within 70 km of Yucca Mountain to the present date. One oblique reverse-slip mechanism for a small earthquake ($M_L = 1.7$) in the Tippipah Spring quadrangle, also mentioned above in the section "unusual mechanisms," has epicenter 35 km northeast of a central point (coordinates $36^{\circ}51'N$, $-116^{\circ}27.5'W$) on Yucca Mountain (Harmsen and Rogers, 1987). That solution has one glaring polarity inconsistency, so our confidence in the solution is low.

Focal mechanisms of other notable SGB earthquakes, 1987 to 1989

The October 2, 1987, 11:11 UTC, magnitude 3.4 earthquake in the Papoose Lake SE quadrangle (Table 3, Index 9) yields focal mechanisms that vary significantly as a function of assumed depth-of-focus. The nearest station is over 27 km from the epicenter, so depth resolution is necessarily poor. In Appendix D, two mechanisms are presented, one for an assumed five km below sea level focus shown in Figure D11, and the other for an assumed 11 km below sea level focus shown in Figure D12. RMS travel time residuals are of little help in narrowing down the hypocenter, being 0.19 sec for the shallower-focus solution and 0.20 sec for the deeper-focus solution when using the standard SGB crustal model. Both hypocenters' focal mechanisms possess a northwest-dipping and southeast-dipping nodal plane. The southeast-dipping nodal plane for the shallower-focus hypocenter dips at about 14 degrees, providing another example of a possible seismically active detachment fault. The northwest-dipping nodal planes for both solutions dip steeply, and are oriented favorably for normal slip if the extensional direction is north-northwest in the vicinity of the hypocenter. The earthquake was somewhat unusual in that only two other hypocenters were observed in its vicinity over the next month, an unusually low level of concomitant seismicity for an earthquake of its magnitude.

Focal mechanisms for a $M_L = 2.0$ Yucca Flat earthquake on February 7, 1988, (Table 3, Index 14) show strong dependence of strike, dip, and rake on assumed depth of focus. When treated as a surface-focus event, the focal mechanism indicates oblique slip on a steeply-dipping north-south fault (Yucca Fault?), or strike slip on an east-west oriented fault (Figure D18). When treated as a deeper-focus event, five km below sea level, the focal mechanism includes a 5° northwest dipping nodal plane, with strike-slip motion, and a northwest-oriented vertical nodal plane with vertical motion (Figure D19). The possibility of a seismic detachment fault thus reappears, although this example suffers from a poorer data fit to the velocity model, with RMS travel time residual = 0.20 seconds for the deeper hypocenter, versus 0.14 seconds for the surface-focus hypocenter. A graph of how the RMS travel time residual varies as a function of depth-of-focus when using HYPO71 to determine the hypocenter of this Yucca Flat earthquake is shown in Figure 14. The surface-focus solution is not particularly satisfying to many seismologists, who believe that ultra-shallow rock is generally not strong enough to store sufficient distortional strain energy for magnitude 2 earthquake generation. Thus, the relatively large travel time residual for the deeper focus solution may be more the result of an inadequate velocity model for this earthquake's arrival time data set than of an intrinsically poorer depth-of-focus estimate.

The Reveille Peak quadrangle earthquake of October 28, 1987, 17:25 UTC (Table 3, Index 10), is one of the larger ($M_L = 2.8$) of a few hundred earthquakes observed in a few km zone at the southern end of the Reveille Range from 1986 through 1989. The nearest seismic station to this series, QCS, is about 21 km east, so depth of focus is poorly resolved for these earthquakes. A rangefront fault on the west side of the Reveille Range may be active in the Quaternary, and may be associated with this long-running series. Focal mechanisms were computed for a near sea level focus,

Figure 14.— *Left side:* epicentral scatter for various fixed depth and free depth HYPO71 hypocenters for a Yucca Flat earthquake of February 7, 1988, 16:47 UTC. The symbols correspond to the fixed depth hypocenters: M,0,1,2,..., A,B,C,D,E, and F for depths = -1,0,1,2,...,10,11,12,13,14, and 15 km below sea level. The open square is for the free depth solution, with starting iterate depth 7 km, and the Z is for the free depth solution with starting iterate depth 0 km (at sea level). *Right side:* The RMS travel time residual for the various fixed depth and free depth solutions for the same event. The letters above the fixed depth solutions, and below the free depth solutions, are HYPO71 “grades” assigned during the process of hypocenter determination. This plot shows a small variation in *RMS* for many shallow depth estimates, a pattern that is often present for SGB data sets where the nearest station is relatively distant from the epicenter.

and for a 5.7 km below sea level focus. The shallower-focus focal mechanism solutions, shown in Figure D13, indicate right-lateral strike slip on a steeply dipping north-trending fault, or left-lateral strike slip on a steeply dipping west-trending fault. The deeper-focus focal mechanisms shown in Figure D14, are less well constrained, but all solutions have a significant component of reverse slip on northwest-trending nodal planes, and a steeply plunging tension axis. Another earthquake in the southern Reveille Range series, occurring on August 30, 1988, at 2:30 UTC, has an oblique normal-slip strike-slip solution for a fixed-depth hypocenter at five km below sea-level, shown in Figure D36 (Table 3, Index 20). The near-surface layer velocities used for hypocenter determination were two to 25% faster than those of the standard model, based on observed negative travel-time residuals for stations north of Yucca Flat and Rainier Mesa nuclear device tests, relative to the standard velocity model.

A strike-slip earthquake occurred on January 9, 1989, 05:08 UTC, with epicenter about 10^+ miles (17 km) north of Las Vegas, Nevada (Valley quadrangle), where it was strongly felt ($M_L^H = 3.5$; $M_L^{NEIC} = 3.5$; MMI= V to VI, Carl Stover, written communication). This is the only SGB earthquake during the 1987-1989 period for which property damage was reported to the National Earthquake Information Center (NEIC), although damage was slight (cracked windows). The focal mechanism solutions shown in Appendix D, Figure D29 and D30, indicate right-lateral strike slip on a steeply dipping north-trending fault, or left-lateral strike slip on a west-trending fault. The epicenter is in an alluvial valley at the base of the south flank of Gass Peak, with no immediately obvious fault to identify as the source. The inferred Las Vegas Valley fault strikes west-northwest in the vicinity of the epicenter, but SGBSN first-motion data do not fit the local trend of that fault. Variations in assumed focal depth for this earthquake have little effect on the focal mechanism solutions. For example, the angle of slip on the east-west nodal plane is $0^\circ \pm 15^\circ$ for a seven km below sea level hypocenter; it is $7^\circ \pm 8^\circ$ for the four km below sea level hypocenter shown in Figure D29; it is $-5^\circ \pm 3^\circ$ for solutions derived from a hypocenter at sea level, shown in Figure D30 (0° represents horizontal block movement). This earthquake is one of the few observed for the 1987 through 1989 period for which the regional SGBSN network P-wave polarities provide a fairly well-constrained set of focal mechanisms, relatively independent of assumed hypocentral depth.

In this section, focal mechanism solutions for four SGB earthquakes that occurred between 1987 and 1989, all having magnitude ≥ 2.0 , have been discussed, with emphasis on the variety of solutions that result by changing the assumed hypocentral depth. In only one case, that of the January, 1989, earthquake north of Las Vegas, Nevada, was the focal mechanism solution set not strongly affected by changing the assumed earthquake depth of focus by a few km. In some cases, depth uncertainty translates primarily to nodal plane dip-angle uncertainty, and seismically active detachment faults become possible source interpretations. In some cases, predominantly strike slip solutions change to predominantly reverse slip solutions by increasing the assumed depth of focus. Although the earthquakes for which these ambiguous source interpretations are > 50 km distant from Yucca Mountain, they are often the mainshocks of relatively important earthquake clusters. These observations point to the need to put temporary portable networks over seismically active spots in the SGB if we wish to better understand seismotectonic processes in the region surrounding a potential national nuclear waste repository at the Yucca Mountain site.

Average directions of \vec{P} and \vec{T} and tectonic strain

When considered collectively, the focal mechanisms for SGB earthquakes provide a fairly consistent descriptor of certain components of the regional tectonic strain tensor at shallow to mid-crustal depths. Figure 15 is a plot of the thirty pressure axes (P or \vec{P}) and tension axes (T or \vec{T}) for the 1987-1989 mechanism primary solutions listed in Table 3. The pressure axes form a girdle or belt through the hemisphere, and the tension axes cluster in the northwest and southeast quadrants, with relatively small plunge angles. When using Watson's eigenvalue/eigenvector analysis of directional

data on the sphere (Schuenemeyer and others, 1972), we obtain an *average* tension direction, $\text{azi}(\vec{T})$, of N59°W, with plunge 2.8°, for the data of Table 2. (Each datum was weighed equally, regardless of earthquake magnitude or degree of constraint on mechanism parameters.) When excluding the Silent Canyon caldera focal mechanisms, whose sources may be induced by nuclear device tests, the azimuth of $\text{avg}(\vec{T}) = \text{N}55^\circ\text{W}$, with plunge 2.8°. Figure 16 is a plot of the pressure and tension axes for previously published SGB earthquake focal mechanism data for the period 1979-1986 (Rogers and others, 1987, and Harmsen and Rogers, 1987). For these earlier data, $\text{azi}(\vec{T}) = \text{N}57^\circ\text{W}$, with plunge = 2.0°. The distributions are very comparable. The average T-axis is the seismically determined direction of average minimum principal compressional strain within the seismogenic crust, and is sometimes taken as an approximation to the direction of minimum principal compressional tectonic stress. Furthermore, the $\text{avg}(\vec{T})$ azimuth corresponds remarkably well with the direction of net Great Basin extension as determined from space geodesy and neotectonic constraints, $\text{N}56 \pm 10^\circ\text{W}$ (Minster and Jordan, 1987).

The focal mechanism $\text{avg}(\vec{T})$ is rotated about 15° clockwise from the direction of net Neogene extension from the Las Vegas fault system to the Death Valley fault system, as geologically determined, $\text{N}73 \pm 12^\circ\text{W}$ (Wernicke and others, 1988), although the significance of this observation is not known.

Focal mechanisms provide relatively cheap indicators of tectonic stress parameters, but because of the multiple uncertainties in depth of focus, focal mechanism strike, dip, and slip, the particular mechanics of each fault (strength, friction, fluid pore pressures in fault zone, fault interactions), and the variability of the stress tensor with position due to crustal heterogeneity, there is no mathematically well-defined mapping between focal mechanism data and the crustal stress tensor. The majority of SGB focal mechanism solutions computed to the present date certainly conform to the model of a highly stressed shallow crust (earthquakes are triggered by many NTS nuclear device tests) in which the horizontal stress in the northwest to west-northwest direction is substantially reduced, releasing gravitational energy through normal faulting events on northeast trending faults and releasing horizontal strain energy through strike slip motion on steeply dipping, generally north-trending, faults. The mechanics permitting seismic slip on sub-horizontal (detachment) faults does not fit this conventional model.

Some of the earthquake focal mechanisms whose \vec{T} axes differs markedly from the average \vec{T} may be called "outliers." Outliers include (1), events with oblique to near-vertical \vec{T} plunge angle, and (2), events with \vec{T} 's azimuth rotated significantly from the northwest-southeast direction. An example of an event having a 50°-plunging tension axis is the Furnace Creek eathquake of March 16, 1982, discussed briefly in an earlier section. Examples of events with obliquely inclined \vec{T} (i.e., $\text{plunge}(\vec{T}) \approx 45^\circ$) are discussed in the section on possible active detachment faults, above. Examples of events having rotated $\text{azi}(\vec{T})$ include the Yucca Mountain mechanism for earthquakes on October 18, 1988, two Silent Canyon Caldera earthquakes discussed above, and the composite Timber Mountain mechanism for earthquakes on July 3, 1988 and July 24, 1988 shown in Appendix D, Figure D24. The focal mechanism for the Owens Valley earthquake of July 5, 1988, shown in Figure D23, has $\text{azi}(\vec{T}) = \text{N}105^\circ\text{W}$ (longitude 118.05° W), and that of the Dry Mountain quadrangle earthquake of May 26, 1988, shown in Figure D20, has $\text{azi}(\vec{T}) = \text{N}83^\circ\text{W}$ (longitude 117.71° W), providing evidence for the possible counterclockwise rotation of the direction of minimum crustal compression at the western edge of the SGB, in the vicinity of the Sierra Nevada block boundary, relative to the central SGB. Another southwest SGB hypocenter with a focal mechanism having $\text{azi}(\vec{T}) \approx$ east-west is that for the Stovepipe Wells quadrangle earthquake of July 8, 1986, 03:02 UTC (Harmsen and Rogers, 1987). The northwest-southeast orientation of the Furnace Creek fault, northern Death Valley, California, may be favorable for right-lateral strike slip if the extensional direction is more east-west than would be suggested by the *average* strain tensor for SGB earthquakes, and if north-south crustal compression is sufficiently great in its vicinity. Very extensive sets of focal

SGB earthquakes 1987–1989

mechanism solutions (hundreds) have been determined for the seismically active Mammoth Lakes, Round Valley, Chalfant Valley, and Mono-Walker Lake regions, as well as for central Nevada, and are used to infer crustal stress tensor rotation from central Nevada ($\approx 39.5^\circ$ N, 118° W) to the Sierra Nevada rangefront ($\approx 37.5^\circ$ N, 118.8° W) (Vetter, 1990). A clear counterclockwise rotation of σ_3 , the minimum principal compressive stress, is evident from the Central Nevada Seismic Zone, where the inferred σ_3 azimuth is approximately N 50° W (plunge negligible), to Mammoth Lakes, where the inferred σ_3 azimuth is approximately N 100° W (plunge negligible) (Vetter, 1990).

Depth-of-focus distribution and deep-crust intraplate earthquakes

A widely-held view on the depth distribution of earthquakes in the Great Basin is that depths should be confined to the upper 15 km or so of crustal rock, with local variations based on higher-than-average or lower-than-average heat flow, different lithologies, and strain rates (Smith and Bruhn, 1984). The vicinity of 15 km depth is frequently termed the brittle-ductile transition zone. The SGBSN hypocenter catalog generally conforms to this model, in that less than two percent of the reported earthquake hypocenters for the 1987-1989 period have estimated depths, z , greater than 15 km below sea level. This property generally holds for depth distributions in other parts of the Great Basin where hypocenter data are available, with the exception of the Truckee, California, region, where depths of focus often lie between 15 and 20 km (Rogers and others, 1989). Figure 17 shows the frequency distribution of depth-of-focus of a subset of earthquake hypocenters from Appendix A of this report having the properties that the minimum source to station distance < 10 km, the standard error in depth, $err_z < 5$ km, and the HYPO71 average grade (Avg(Q1,Q2) in Appendix A listing) is C or better. Although these restrictions are not enough to insure well-constrained hypocenters, they reduce the population from $N \approx 3300$ to $N = 851$, and therefore result in a sample of what may be the best-constrained quartile of the population of 1987 through 1989 SGB hypocenters. Figure 17(a) shows a bar graph of the counts of such events in each 1-km interval, from one km above sea level to 20 km below sea level. Figure 17(b) shows the probability distribution of depth of focus for that sample, where cumulative probability within each interval is assigned by assuming that "depth" for the i th hypocenter is a normally and independently distributed random variable, with mean z_i and standard deviation err_{z_i} , respectively. The values z_i and err_{z_i} are the depth and standard error in depth, as reported in Appendix A. Also, the tails of the normal distributions are truncated at one km above sea level and 20 km below sea level, and any remaining area under the probability curves beyond those limits is accumulated into those extreme intervals. (A more realistic probability density function would, of course, have finite tails, with limits corresponding to the bounds of the seismogenic crust.) The distributions of Figure 17 are comparable to those reported in previous SGBSN data reports (Rogers and others, 1987, and Harmsen and Rogers, 1987). Although the "fine structure" of the distributions may be more a function of the location algorithm and velocity model than of any fundamental property of the earth's seismogenic crust, the main feature, a rapid tapering off of seismic activity at depth > 12 km, is probably real.

Of the relatively deep-focus hypocenter solutions for earthquakes in the SGB, very few depths are in the relatively well-constrained upper quartile as defined in the preceding paragraph, the typical deep hypocenter being from a data set having a source-station gap $> 180^\circ$ and the nearest station > 25 km from the source. A very small subset of the deep-crust hypocenters is well-located, having both primary and secondary arrivals available at a station within 15 km of the epicenter, relatively low RMS residual, reasonable V_P/V_S ratio, and $\leq 180^\circ$ gap in station azimuthal coverage. The V_P/V_S ratio is the ratio of primary to secondary wave velocity, as inferred from P-wave and S-wave arrival times at recording stations. For the period 1987 to 1989, the deepest hypocenter meeting all of these criteria is that of a magnitude one earthquake on August 21, 1989, 16:17:45 UTC, in the Halfpint Range, eastern NTS (Paiute Ridge quadrangle). The hypocenter is about 30 km below sea level, at a depth corresponding to the crust-mantle interface. Seismograms from the 12 nearest SGBSN stations that recorded this earthquake are displayed in Figure 18, with their corresponding P

Figure 17.— Depth of focus distribution of the best-constrained upper quartile of SGBSN hypocenters for the period 1987 through 1989 (see text for definition of “best-constrained”). (a) Graph of counts of events versus focal depth, in one km intervals. (b) Graph of probability that an event occurs within a given one-km interval in the depth range $-1 < z < 20$ km, where negative depths are understood to be above sea level (see text for discussion of how probabilities are determined).

Figure 18.—Seismograms from a deep-crustal earthquake on August 21, 1989, 16:17:45 UTC, in the eastern NTS (Paiute Ridge quadrangle) are displayed for 12 SGNSN stations nearest to the epicenter. The total time between the left and right brackets is 56 seconds. Scaled arrivals for primary (P) and secondary (S) waves are also displayed. The S – P time for the nearest station, GLR, is 4.30 seconds.

Figure 19.— *Left side*, epicentral scatter, and *right side*, behavior of *RMS* function, as a function of assumed depth of focus for HYPO71 hypocenters for an eastern NTS deep-crustal earthquake of August 21, 1989, 16:17 UTC. The symbols in the epicenter plot, M, 0,1,2, ..., A,B,C,D,E,F now represent fixed-depth epicenters for solutions having depth 15, 16, 17, 18..., 26, 27, 28, 29, 30, and 31 km below sea level, respectively. The open square, arbitrarily plotted at (0,0), is the epicenter for a free-depth solution, with initial iterate depth 7 km, and the “Z” symbol is the epicenter for a free-depth solution with initial iterate depth 0 km. All epicenters are plotted relative to the position of the square

Figure 20.— *Left side*, epicentral scatter and *right side*, behavior of *RMS* as a function of fixed-depth and free-depth HYPO71 solutions, with symbols having same meanings as in Figures 10 and 14, for an earthquake north of Las Vegas, Nevada, on December 31, 1987 8:12 UTC having probable depth of focus near the brittle-ductile transition. (a) Hypocenters derived using a model with no interface at 15 km below sea level, $V_p = 6.15$ km/sec between 3 and 24 km below sea level, (b) Hypocenters derived using a model with an interface at 15 km below sea level, $V_p = 6.5$ km/sec below that interface (see Figure F1(a) for the velocity model). This figure shows that in some instances, the 15 km interface, or the relatively high velocity below that interface, is not well supported by arrival time data.

In summary, deep crustal earthquakes in the SGB are both rare and small (maximum magnitude = 1). Data quality of those earthquakes' seismograms is poor, probably due in part to peculiar source properties and to relatively high P-wave and S-wave attenuation (low Q) of rock at mid-crustal to deep-crustal depths. To depths of about 15 km below sea level, SGB microearthquakes yield seismograms that contain relatively high energy content in the 5-10 Hz range, whereas seismograms of microearthquakes originating at greater depths are depleted in those frequencies. Focal mechanism solutions have not been attempted for the data of deep-crustal SGB earthquakes, due to the ambiguity of P-wave onsets at SGBSN stations.

Conclusions

- Although epicentral constraint on most SGB earthquake locations is fairly good (probable epicentral error ≤ 1 km), hypocenter (depth-of-focus) constraint is often poor (uncertainty in depth frequently on the order of 5 km). A more accurate velocity model could reduce depth uncertainty, but in its absence, and given the high degree of structural variability of SGB rock, a denser seismographic network is necessary.
- An important consequence of depth-of-focus uncertainty is that focal mechanism solutions, even if well-constrained for a given assumed depth, sometimes vary significantly with changes in depth. However, some SGB focal mechanism parameters, especially the azimuth of the tension axis, are relatively stable or "robust" for those different solutions.
- Deep-crustal earthquakes in the SGB are rare (less than 2% of the total hypocenters) but not non-existent. Their presence at the crust-mantle interface (≈ 32 km) provides an intriguing geophysical problem in a high heat-flow region.
- SGB earthquake focal mechanism solutions are generally strike-slip, oblique slip, or normal-slip, in roughly equal proportions, with tension axes clustering in the northwest-southeast quadrants, with relatively small plunge angles, and pressure axes forming a girdle or belt through the focal hemisphere. These solutions suggest a uniform crustal stress pattern in which compressional stress in the northwest-southeast direction is substantially lower than in other directions. Gravitational energy is released through normal faulting events on north-northeast to northeast trending faults and horizontal strain energy is released through dextral motion on steeply dipping, north trending faults and through sinistral motion on east-northeast trending faults. The mechanics permitting seismic slip on sub-horizontal (detachment) faults does not fit this conventional model.
- Exceptional focal mechanism solutions, including solutions having a nodal plane with dip $< 20^\circ$, strongly rotated tension axis direction, or reverse slip are encountered in the 1987-1989 SGB data. They do not conform to the regional pattern, and some may indicate local anomalous tectonic features. No unequivocal, predominantly compressional focal mechanism solutions have been determined from SGBSN data for earthquakes within 70 km of Yucca Mountain through 1989.
- SGB focal mechanism data are consistent with crustal stress models which display regional counter-clockwise rotation of principal horizontal stress directions from the California-Nevada stateline at 36°N to 37°N , and $\approx 116^\circ\text{W}$ to 117°W to the eastern Sierra Nevada block boundary at about 118.1°W .
- Yucca Mountain, Nevada, is a seismically quiet site relative to surrounding areas. Focal mechanisms for Yucca Mountain earthquakes are difficult to constrain, because no Yucca Mountain earthquakes yet recorded have size greater than $M_L = 2.1$, and most have $M_L < 1.0$.
- Rock at shallow depths in the vicinity of Rainier Mesa displays a strong directional anisotropy for P-wave velocities; whether this apparent anisotropy is the result of aligned cracks and stresses or of the presence of crustal heterogeneity, i.e., a high-speed ridge under Rainier Mesa, is not determinable

from P-wave arrival data alone. The ability to distinguish among competing explanations could be achieved by an analysis of shear wave splitting from on-scale, three-component recordings of nuclear device detonations which release tectonic strain over a range of azimuths; such data are not available from the current SGBSN.

Appendix A

Earthquake locations for the years 1987, 1988 and 1989 and quadrangle map names to which locations are keyed

All earthquake hypocenters reported in Appendix A are preliminary. The local hypocenter summary column headings are for the most part self-explanatory. UTC is Universal Coordinated Time. Horizontal error equals $\sqrt{sdx^2 + sdy^2}$, where sdx and sdy refer to the HYPO71 standard errors in longitude and latitude, respectively. Vertical error is the HYPO71 standard error in depth (sdz). "AZI GAP" is the azimuthal gap, that is, the largest angle subtended by the epicenter and any two circularly adjacent stations with positive phase weight. "Q1" and "Q2" represent two HYPO71 hypocenter quality estimates as defined by Lee and Lahr (1975). "DS" is a code for data source: A for analog seismograms, (data scaled from developorder films, starting depth, z_0 , at 7 km for iterations), all other letters are for data scaled from digital seismograms. Five digital data letters are defined: Z, S, and T are for minimum RMS travel time residual solution having $z_0 = 0, 7$, or 12 km below sea level, respectively, using the standard SGB crustal velocity model, modified to include a layer interface at 15 km, below which $V_P = 6.5$ km/sec; I is a solution using the standard SGB model without the 15 km interface, and Y is a solution using the Yucca Mountain velocity model. In each of the latter cases, $z_0 = 7$ km. for the initial hypocenter guess. x_0 and y_0 are always taken to be near the earliest-reporting station. When equal final RMS values occur for solutions having different z_0 , the priority for reporting is I, S, Z, and T. A and Y solutions were not extensively redetermined using different values of z_0 .

M_{ca} is the coda-average magnitude, M_d is the duration magnitude estimate, M_{lh} is local magnitude from horizontal-component instruments, M_{lv} is local magnitude from vertical-component instruments, M_{lc} is the maximum of station magnitudes from overdriven (clipped) records. Amplitudes recovered from vertical-component data are multiplied by 1.75 to provide an approximate horizontal-equivalent amplitude. M_{ca} is computed from the post-S coda by fitting the envelope function,

$$A(t) = A_0(t - t_p)^{-1.8},$$

to a sequence of 5.12-second windows of peak amplitude data in the unclipped portion of the seismogram. In this formula, A_0 is statistically determined, and is transformed into M_{ca} . The modeled time rate of decay is governed by the exponent 1.8, which lumps geometric spreading, scattering, and anelastic attenuation. M_{ca} appears to underestimate the true event magnitude when $M > 2.7$.

Depth estimates may be followed by one or two stars. One star means that the depth-of-focus standard error estimate was very large (\geq half crustal thickness). Two stars imply that the depth was fixed by HYPO71 during the last several iterations for hypocenter, because the data lacked resolving power for that parameter. In some instances, the standard depth error estimate, sdz is followed by one or two +s. These cases, discussed in greater detail in the section, Preliminary hypocenter determination for SGB earthquakes and explosions, are for hypocenters whose depth-of-focus uncertainty is greater than would be suggested by sdz .

DELMIN is the minimum source to station distance in km, and RMS RES. is the root-mean-square travel time residual, defined in the text of this report. #N PH. is the number of (P+S) phases having positive weight in the solution. Finally, U.S.G.S. quadrangle is the name of $7\frac{1}{2}$ or 15 minute topographic quadrangle in which the epicenter lies. Regional events are not assigned quadrangle names.

Figure A1.—Quadrangle names in the northeast quarter of the southern Great Basin

Figure A2.— Quadrangle names in the southeast quarter of the southern Great Basin.

Figure A3.- Quadrangle names in the northwest quarter of the southern Great Basin.

Figure A4.- Quadrangle names in the southwest quarter of the southern Great Basin.

Figure A5.— Map tabulating maximum earthquake magnitude (M_L where available, otherwise M_D or M_{ca}) in each $7\frac{1}{2}'$ quadrangle within the ranges 114.875°W to 117.875°W and 36.125°N to 38.125°N recorded by the SGBSN. The *top* number is the maximum magnitude in the period 1987 through 1989, and the *bottom* number is the maximum magnitude in the period August, 1978 through December 1986. The letter “Q” (quiet) within a quadrangle means no earthquakes were monitored during that period by the SGBSN. The NTS boundary and part of the California-Nevada state border are shown. Alternate rows are shaded to aid in visual separation of information in adjacent quadrangles.

Appendix B

Chemical explosion location data for the years 1987, 1988, and 1989

The southern Great Basin of Nevada is seismically active from both natural and man-made sources. Chemical explosion seismic data acquired by the SGBSN have been scaled to provide information on the accuracy of the crustal models and the validity of the location algorithm used by the SGBSN. These data should also be helpful in future research such as tomographic inversion of P-arrivals to determine crustal structure.

Employees from the following organizations have been contacted and have provided helpful information on source locations, times, and in some cases, TNT-equivalent source size:

- (1) Bond International Gold, Denver, Colorado. Blasting at Ladd Mountain, Nev. (Bullfrog Hills quadrangle), approximately daily (weekdays, 4 PM to 5 PM).
- (2) Chemstar, Inc., Las Vegas, Nevada. Blasting at two limestone quarries, one in the Dry Lake, Nevada, quadrangle, and one in the Sloan, Nevada, quadrangle.
- (3) Cyprus Tonopah Mining, Tonopah, Nevada. Blasting in the San Antonia Mountains (San Antonia Ranch quadrangle), usually in the AM.
- (4) Frehner Construction, North Las Vegas, Nevada. Blasting at limestone quarry in Sloan, Nevada, quadrangle.
- (5) Saga Exploration Co., Beatty, Nevada. Blasting at Bare Mountain, Nevada usually early to late afternoon.
- (6) U. S. Geological Survey, Menlo Park, California. Chemical explosions during January, 1988, in Amargosa Desert, Nevada, for seismic reflection feasibility survey. See Brocher and others, Table 3 (1990), for shot information.

A number of other organizations are also known to be engaged in blasting in the southern Great Basin of Nevada, but have not been contacted.

Column headings for this Appendix are identical to those for Appendix A. The depth of all blasts is at the surface (plus < 100 feet, usually), but in many instances, hypocenters have been located with depth as a free parameter, to examine the location algorithm and velocity model. If the hypocenter depth is reported as -1.00, it was fixed at that value during hypocenter determination. All other depths are freely determined. If the letters "PB" follow the depth estimate, the event is a probable blast, but just enough ambiguity was present in the seismograms to prevent a certain judgment. Far more hypocentral data from chemical explosions than are presented in this Appendix have been detected and archived by the SGBSN, especially for years preceding 1989. The decision was made in late 1988 to scale arrival time and amplitude data and to include all resulting hypocenters for known and probable blasts into the catalog, but to flag them as blasts (or probable blasts).

Figure B1. Preliminary epicenter map of blasts and probable blasts in the SGB, 1987 through 1989.

Appendix C

Nuclear device tests and low-frequency shallow seismicity in the SGB, 1987 through 1989

Hypocenter data for announced Nevada Test Site nuclear device tests occurring in 1987, 1988, and 1989 are listed in Table C1 and corresponding epicenters are shown in map view in Figure C1. Hypocenter parameters are listed as they are reported to the National Earthquake Information Center (NEIC) by the Department of Energy. Magnitude estimates are provided by Berkeley Seismographic Laboratory or by the NEIC. SGBSN stations generally record nuclear detonation ground motions well beyond their dynamic range; thus, only initial P-wave arrival times can be reliably scaled from SGBSN seismograms of nuclear tests.

When observed travel times (OT_i) are compared with theoretical values (TT_i , corresponding to source to station rays computed from the standard velocity model used to locate SGB earthquakes, shown in Appendix E), the resulting residuals or "delays" ($D_i = OT_i - TT_i$) provide insight into the P-wave velocity structure of shallow crust. Figures C2, C3, and C4 are contour maps of percent velocity variation from the standard model, as implied by the delays observed for tests "Alamo," "Disko Elm," and "Kawich," respectively. The contour levels are interpolations/extrapolations onto the entire SGB of $\Delta V(\%) = -100D_i/OT_i$, $i = 1, 55$, where D_i is the i th delay (sec). for SGBSN station recordings of primary waves from a given nuclear device test. The reader is cautioned that the mapped patterns of velocity variation result from "heavy-handed" interpolation and extrapolation from a very limited station data base. Station coverage within the Nevada Test Site and at Yucca Mountain is many times better than elsewhere in the southern Great Basin with the consequence that patterns in the variation of shallow crustal velocity in the immediate vicinity of NTS are more reliable than those away from NTS.

Relatively high levels of ultra-shallow seismicity are regularly recorded by SGBSN stations for periods ranging from hours to days following NTS nuclear device tests. The seismicity listed in Appendix C consists of such events, which have characteristically lower-frequency seismic P coda and S coda than the vast majority of earthquakes in the SGB, and are designated "LFEs." Most of the LFEs can be associated with nuclear device testing at Pahute Mesa, Yucca Flat, and in a few instances, at Rainier Mesa. Some of these events may be identified as *the collapse* of a given test. The heightened level of post-test LFE seismicity often continues for days, with no single event having clearly greater magnitude, as determined from SGBSN seismograms, than many others in its vicinity. Data from the majority of these LFEs are archived onto magnetic tapes without being analysed by SGBSN staff. An unexamined assumption about the nature of these low-frequency northern NTS events is that *all* of them are ultra-shallow aftershocks resulting from anomalous local conditions generated during nuclear device tests.

Apart from the LFE seismicity, it is possibly true that the natural seismicity rate in the SGB also increases for several days following some NTS tests, especially if the time interval between NTS tests is several months. That NTS tests might trigger earthquakes for several days at distances on the order of 50 to 100 km is a hypothesis that the current catalog should be able to address. This topic is an area of current research.

A few low-frequency events that do not locate at NTS are included in Appendix C, because their seismic coda appears more similar to post-test, collapse-like seismicity than to earthquake coda. Many of these are undoubtedly blasts in unconsolidated alluvium or intensely fractured tuff. The verification that other explanations of these phenomena are invalid is left to future investigation.

Figure C1. Map of announced NTS nuclear device detonation epicenters for the period 1987 through 1989 (test epicenters are octagons), and of epicenters of a small subset of the low-coda frequency activity (aftershocks?, collapses?) that followed those UNEs (designated by "L" symbols).

Figure C2. Contour map of percent P-wave horizontal velocity variation, ΔV , from velocities obtained from the standard model shown in Figure F1(a) for arrival time delays from the test "Alamo," detonated on July 7, 1988, 15:05:30.07 UTC, in the Silent Canyon Caldera. ΔV s from stations nearest the four corners of the map have been inserted at the map corners to suppress the formation of spurious contours near the edges of the map. (Interpolation of the ΔV s computed at SGBSN station locations to a 42×42 grid over the entire SGB is performed using the International Mathematical and Statistical Library routine "IQHSCV.")

Figure C3. Contour map of percent P-wave velocity variation from the standard model shown in Figure F1(a) for SGBSN station data from the tunnel test "Disko Elm," detonated on September 14, 1989, 15:00:00.10 UTC, at Rainier Mesa. The same data reduction was performed as in Figure C2.

Figure C4. Contour map of percent P-wave velocity variation from the standard model shown in Figure F1(a) for SGBSN station data from the test "Kawich," detonated on February 24, 1989, 16:15:00.08 UTC, at western Yucca Flat. The same data reduction was performed as in Figure C2.

NOTES: Coordinates of announced tests are supplied to the National Earthquake Information Center, Golden, Colorado (NEIC), by the Department of Energy. These coordinates have been rounded to the nearest 0.0001 degree in Table C1. The ML estimates (local magnitude) are provided by the Berkeley Seismographic Laboratory (BRK) or by the NEIC. Depth is the reported working point depth, relative to sea level (negative z above sea level).

Appendix D

Earthquake focal mechanisms 1982 and 1987 through 1989

The focal mechanisms of Appendix D were obtained by selecting the best-fitting solution(s) from the application of the computer program "FOCMEC" (Snoke and others, 1984) to the ray data generated by HYPO71, and in some instances, to amplitude data. We plot data on the lower focal hemisphere using the equal-area projection (Lee and Stewart, 1979). The symbols represent first-motion P -polarities, and their positions represent the points where the HYPO71-determined raypaths intersect the focal hemisphere. The darkened circles represent impulsive compressional arrivals, the + symbols represent emergent compressionals, the open circles represent impulsive dilatational, the - symbols represent emergent dilatational, and the \times symbols represent indeterminate or nodal readings. The + symbol at the center of each mechanism is *not* a compression; it is a point of reference for readers who may wish to search for alternative solutions using a Schmidt net. SGBSN station names are printed adjacent to the first-motion symbol for many of the solutions presented in Appendix D. In the following figures the P and T symbols represent the pressure and tension axes, respectively. The X and Y symbols represent slip vectors for each nodal plane, and B is the null axis. Primed P and T symbols are the respective vectors for alternate (dashed) solutions when they are presented. Some mechanisms are composed using data from several events that are clustered in time and space. Composite solutions are noted in each figure. Several examples of focal mechanism solutions for relocated hypocenters at substantially different depths-of-focus are presented to indicate the effect these changes have on strike, dip, and rake.

For several mechanisms, the information contained in P-wave polarities was not adequate to effectively constrain the nodal planes. In these instances, first motion P- and SV- amplitude data were gathered at selected stations, indicated by a large square around the polarity symbol. The observed and theoretical $\log_{10}(SV/P)_z$ ratios and the difference between the logarithms of observed and theoretical ratios are computed for hundreds of potential solutions whose nodal planes conform to P-wave first-motion polarities. The theoretical values shown in each figure are for the "optimum" solution shown, having the lowest rms error and fewest polarity inconsistencies. If the difference between observed and theoretical values is greater than a specified limit, err_{max} , that station's amplitude data are not used in the solution and an asterisk is placed by its name in the solution table. We always set $err_{max} \leq 0.3$, corresponding to a maximum factor between theoretical and observed amplitude ratios of 2.0.

Kisslinger and others (1981 and 1982) and Rogers and others (1987) discuss several assumptions that must be satisfied for the $(SV/P)_z$ amplitude ratio method to be valid. Their comments and observations are included herein by reference.

This earthquake's focal mechanism
 is constrained by several P-wave
 arrivals from stations in the
 southern California seismic network,
 archived in their CUSP system, event 7461.
 ML is taken from Pasadena, also reported
 by Berkeley as ML=3.7.

This earthquake was felt at Alamo, Nevada. Its focal mechanism is well-constrained by P-wave first motions, including polarity data from station DWU, operated by the Seismograph Stations of the University of Utah, Salt Lake City, Utah. Station CDHI has the only polarity error for the range of focal mechanisms shown.

Figure D2. Oblique normal-slip focal mechanism solutions for an earthquake of January 13, 1987, in the Pahranagat Shear Zone, that was felt at Alamo, Nevada.

Figure D3. Predominantly strike-slip focal mechanism for a very small earthquake of March 10, 1987, at Yucca Mountain, Nevada, constrained by several SV/P_z amplitude ratios.

The range of fault-plane solutions for this composite of three earthquakes from a short-lived swarm in the Grapevine Mountains is narrow when determining raypaths using a SCB velocity model having interfaces at 1, 3, and 15 km below sea level. The counterclockwise rotation of the tension (T) axis from its average direction for SCB microearthquake focal mechanisms should be noted.

Figure D4. A composite, oblique, normal-slip set of focal mechanism solutions for earthquakes of April 8, 1987, in the Grapevine Mountains, California.

This focal mechanism indicates that the
 SGBSN has recorded microearthquake
 P-wave first motions that
 are best fit by nodal planes one of which
 is sub-horizontal. If the hypocenter is correct,
 this earthquake may be evidence for a
 seismically active near-surface detachment
 fault.

Figure D5. A normal-slip focal mechanism solution having one sub-horizontal nodal plane for an earthquake of April 20, 1987, in the northern Amargosa Valley, Nevada (Specter Range SW quadrangle). The RMS-minimizing depth of focus is at the earth's surface.

ALTERNATE HYPOCENTER -> ALTERNATE MECHANISM
 The Specter Range hypocenter of April 20, 1987,
 11:24 UTC had a minimum RMS travel time residual
 of 0.10 seconds for the surface-focus solution
 previously shown, versus a RMS travel time residual
 of 0.14 seconds for this 6.65 km below sea level
 solution. Even for a radically different distribution
 of P-ray take-off angles for the deeper focus solution,
 the possibility of an active detachment fault remains,
 albeit with horizontal slip here, versus normal slip
 in the previous solution.

Figure D6. A strike-slip focal mechanism solution on a sub-horizontal nodal plane for the same earthquake as in Figure D5, in which the focal depth is changed from surface to 6.65 km below sea level.

This hypocenter is the mainshock of a diffuse series of earthquakes in the Pahranagat Shear Zone, occurring at the southwest terminus of the zone, at the southern end of the Pahranagat Range. Constraint is provided by the SV/P amplitude ratio at station DLM. Other nearby stations all have clipped (overdriven) seismograms for this earthquake. The epicenter falls at the east end of a mapped northeast-trending left-lateral strike-slip fault.

The earthquake is the mainshock of a series of about 34 recorded earthquakes from February 1987 through August 1987 about 15 km north-northwest of Scottys Junction, Nev. This hypocenter, which has minimum RMS travel time residual at sea level or shallower, was determined using a modified velocity model in which $V_p/V_s=1.68$, from a Wadati diagram. Also, a Pg interface at 15 km below sea level is present, below which $V_p = 6.5$ km/sec.

Figure D9. A predominantly strike-slip focal mechanism solution for an earthquake of July 13, 1987, 20:10:15, northwest of Scottys Junction, Nevada.

Figure D10. A strike-slip set of focal mechanism solutions for an earthquake of August 13, 1987, 11:46:09 UTC at the southeast edge of the Timber Mountain Caldera, Nevada.

Because the distance between the nearest station (GMR) and the epicenter is 29 km, the depth of focus for this earthquake is very uncertain. The sub-horizontal dip of the southeast-dipping nodal plane is dependent on the correctness of the depth estimate, and, more generally, on the adequacy of the velocity model. If the hypocenter is correct, the focal mechanism is well-constrained, having essentially no alternate nodal plane solutions.

Figure D11. A peculiar normal-slip focal mechanism solution for an earthquake of October 2, 1987, 11:11:55 UTC, at Yucca Flat, Nevada Test Site, in which one nodal plane is sub-horizontal when the depth of focus is assumed to be about 5 km below sea level.

ALTERNATE HYPOCENTER -> ALTERNATE MECHANISM
 For this fixed-z solution, the distance between
 the nearest station (GMR) and the epicenter
 is 27 km. Assuming
 an 11 km below sea level depth, more
 conventional nodal plane solutions
 are found. The RMS travel time residual
 for this 11 km hypocenter is 0.20 sec,
 vs 0.19 sec for the 5.18 km shown previously.

Figure D12. An alternate predominantly normal-slip focal mechanism solution for the same earthquake as in Figure D11, in which the previously shallow-dipping nodal plane now dips at about 30 degrees, when the depth of focus is assumed to be 11 km below sea level.

Focal mechanism solutions for this hypocenter are fairly well constrained using P-wave polarities alone. Note, the dashed-line solution (Var 2') has a shallow dipping nodal plane (dip = 16 degrees), providing an example of the possibility of seismic slip on a detachment fault.

Figure D17. Predominantly normal-slip focal mechanism solutions for an earthquake of January 26, 1988, 18:17:22 UTC, in the Oasis Valley, Nevada (Thirsty Canyon NW quadrangle), one of which has a shallow-dipping nodal plane.

Figure D18. Set of strike-slip focal mechanism solutions for an earthquake on February 7, 1988 16:47:42 UTC at Yucca Flat, Nevada Test Site, in which the depth of focus is assumed to be 0.21 km above sea level.

ALTERNATE HYPOCENTER -> ALTERNATE MECHANISM
 This five-km below sea level hypocenter, with
 epicenter near the surface trace of Yucca Fault,
 has well-constrained nodal planes
 from P-wave polarities, with a polarity
 error at station KRNA, distance 81 km.
 The RMS travel time residual
 for this hypocenter is 0.20 seconds,
 with poorer fit at both the nearest station,
 CPX, and the nearest station with a scaled S
 arrival, EPN. However, with these limitations,
 the nodal planes now include the possibility of
 seismic slip on a detachment surface.

Figure D19. Alternate focal mechanism solutions for the same earthquake as in Figure D18, in which one set of nodal planes dips subhorizontally. For these solutions, the depth of focus is assumed to be 5.03 km below sea level.

This solution assumes a refractor at
 15 km below sea-level, with velco of
 compressional waves = 6.45 km/sec beneath
 the layer boundary. Also, a refractor
 at 24 Km below which alpha = 7.3 km/sec.
 The 15 km refractor was needed to separate
 the dilatations from the compressions.

Figure D20. Normal-slip focal mechanism solutions for an earthquake of May 26, 1988, 3:56:50 UTC, in the Fish Lake Valley, California (Dry Mountain quadrangle).

The hypocenter is derived from a velocity model in which the P-wave velocities in shallow rock are 4.8 km/sec from the earth's surface to 1 km below sea level, 6.0 km/sec to 3 km below sea level, and 6.15 km/sec below the 3 km interface. The higher velocity for ultra-shallow rock, when compared to the standard model, is supported by NTS nuclear device P-arrival residuals at northern SGBSN stations. The depth of focus for this solution was fixed at 5 km below sea level.

Figure D25. Oblique normal-slip focal mechanism solutions for a southwest Reveille Range, Nevada, earthquake of August 30, 1988, 2:30:33 UTC, in which the hypocenter was derived using a velocity model having higher-than-usual velocities for rock at shallow depths.

This hypocenter is the mainshock of a small series of earthquakes in Cactus Flat, north of Pahute Mesa, that were recorded by the SGBSN from Oct 20, 1988 to Nov 16, 1988. Oblique normal slip to strike-slip is indicated on each nodal plane of the focal mechanism.

Figure D26. Oblique normal-slip focal mechanism solutions for a $M_L = 3.1$ earthquake at Cactus Flat, Nevada (Mellan quadrangle) on October 28, 1988, 20:02:50 UTC. That earthquake was the mainshock of a series that lasted nearly one month.

Figure D27. Oblique strike-slip & normal-slip focal mechanism solutions for one of the largest aftershocks in the Cactus Flat, Nevada series on October 29, 1988, 6:37:18 UTC.

Figure D28. Predominantly strike-slip focal mechanism solutions for the $M_L = 2.1$ mainshock of a short-lived series of microearthquakes at a northwest boundary of Yucca Mountain, Nevada (Bare Mountain quadrangle) on November 18, 1988, 20:32:25 UTC. To provide additional constraint on the focal mechanisms, SV/P_z amplitude ratios were included from a foreshock (the mainshock clipped nearby station seismograms).

Figure D29. Strike-slip focal mechanism solutions for a $M_L = 3.5$ earthquake in the southern flank of Gass Peak, Nevada, about 10 miles north of Las Vegas. This earthquake caused slight damage at Las Vegas, Nevada (at least one instance of cracked windows). Focal mechanism solutions are derived from a fixed-depth hypocenter at 4 km below sea level, a minimum RMS-hypocenter.

GASS PEAK SW

DATE&TIME: 890109 5 8 21.46
 LAT: 36.330 LONG: 115.125
 DEPTH, km: 0.00 +/- 4.0 ML: 3.5
 DMIN (km)= 19.8

The earthquake for which this focal mechanism solution set was determined has epicenter 10 to 11 miles (16 to 17 km) north of Las Vegas, Nevada. Slight damage at Las Vegas was reported to the NEIC, Golden, Colorado, including one or more instances of cracked window glass.

The fixed-depth hypocenter for which data were used for these focal mechanisms is not at the minimum RMS travel time residual using SGBSN P and S arrival time data (RMS=0.23 sec for z at sea level).

Figure D30. Alternate, strike-slip focal mechanism solutions for the same earthquake as in Figure D29. Focal mechanism solutions are derived from a fixed-depth hypocenter at sea level, *not* a minimum RMS-hypocenter. The uncertainty or range in plausible strike of the nodal planes attains its maximum when computing focal mechanisms from this shallow-focus hypocenter. Initial P waves from this earthquake at all SGBSN stations except SHRG, the nearest station to the epicenter, display parabolic starts, characteristic of refracted arrivals, suggesting a very shallow source, notwithstanding RMS.

This Silent Canyon caldera earthquake is another example of an almost exclusively dilatational phenomenon, very similar to the earthquake of June 15, 1988, 06:15 UTC, whose focal mechanism is also shown in this report. Many, possibly most, of the earthquakes of the northern half of the Silent Canyon Caldera (SCC) have similar waveforms. These are shallow earthquakes, probably induced by nuclear device tests at Pahute Mesa. These northern SCC events should not be considered when using focal mechanisms to infer properties of the natural regional tectonic stress field in shallow SGB crustal rock.

Figure D31. Normal-slip focal mechanism solution for a Silent Canyon Caldera, Nevada Test Site, earthquake on January 31, 1989, 16:07:17 UTC. The consistently dilatational first motions from SGBSN stations for this earthquake suggest that it may be an implosion rather than the double-couple event shown in this figure. The nearest-in-time nuclear device test in the vicinity was the December 10, 1988, detonation of "Misty Echo" at Rainier Mesa.

This composite focal mechanism includes data from five earthquakes. Of the 63 P-wave polarities used, 5 are inconsistent. The ray parameters for the inconsistent stations, YMT3, YMT4, YMT5, and YMT6, are all very near a nodal plane, however.

Figure D32. Oblique normal-slip focal mechanism solution for a series of Timber Mountain, Nevada Test Site, earthquakes on March 5 and March 6, 1989. The polarity inconsistencies may come from slight variations in the source parameters for the component earthquakes whose data are composited here.

UBEHEBE CRATER

DATE&TIME: 890412 20 24 55.05
 LAT: 37.214 LONG: 117.295
 DEPTH, km: 7.91 +/- 0.4 ML: 3.0

Var 2'	26.30	75.10	-84.80
Var 2''	190.00	20.00	-90.00

This hypocenter is derived from a SGB velocity model having interfaces at one and three km below sea level, as usual, and an interface at 15 km below sea level, below which $v_p=6.5$ km/sec. For this hypocenter, the range of focal mechanisms consistent with all P-wave polarities is narrow, and includes a 20 degree west-dipping nodal plane on which normal slip occurs. Thus, this hypocenter provides another example of the possibility of seismically detectable slip on a detachment surface, this one in the Grapevine Mountains.

Figure D33. Normal-slip focal mechanism solutions for a Gold Mountain, Nevada (Ubehebe Crater quadrangle) earthquake of April 12, 1989, 20:24:55 UTC. Some of the west-dipping nodal planes have $20\pm$ degree dip, but the depth of focus is probably too great to allow the selection of the west-dipping nodal plane as the fault plane due to high confining stress.

This earthquake is the mainshock
 of a long-running series of earthquakes
 southeast of the town of Alamo, Nevada.
 This focal mechanism solution is
 dependent on depth of focus. In particular,
 the southeast-dipping nodal plane has
 greater dip for a deeper hypocenter. Station
 ARUT polarity and arrival time data were supplied by
 University of Utah's Seismographic Laboratory.

Figure D34. Peculiar reverse-slip or strike-slip focal mechanism solutions for a $M_L = 3.6$ earthquake in the Pahranagat Shear Zone, Nevada (Alamo SE quadrangle), having one sub-horizontal nodal plane. Constraint on the set of focal mechanisms consistent with first-motion data is increased by the inclusion of the data from ARUT, a station operated by the University of Utah Seismographic Laboratory. These solutions assumes a hypocenter depth 3.2 km below sea level. If the modeling assumptions are correct, this is another candidate for seismically active detachment faulting.

ALTERNATE HYPOCENTER => ALTERNATE MECHANISM
 Using a fixed-depth hypocenter, with depth at
 seven km below sea level, results in the
 the southeast-dipping nodal plane having
 greater dip than the corresponding nodal plane
 shown in the previous figure for a shallower, free-depth
 hypocenter. The actual depth is uncertain. Station
 ARUT polarity and arrival time data were supplied by
 University of Utah's Seismographic Laboratory.

Figure D35. Oblique reverse-slip focal mechanism solutions for the same Pahranagat Shear Zone earthquake as discussed in Figure D33, where the hypocenter is now fixed at a depth of seven km below sea level. The arrival time data do not provide an well-constrained estimate of the hypocentral depth for this earthquake.

Figure D37. Predominantly normal-slip focal mechanism solutions for a Mt. Dunfee, Nevada (Scottys Junction SW quadrangle) earthquake on August 28, 1989, constrained by SV/P_z amplitude ratios as well as P-wave first motions.

Appendix E

Station codes, locations, and instrumentation

Appendix E contains a list of SGBSN station names, coordinates, and other descriptive information. Instrument codes refer to the seismometer, amplifier/VCO, and discriminator packages for each station. For the current network, codes 1 through 7 are valid. Any other codes are for systems having unknown frequency response, which are no longer operating in the SGBSN. The following table shows the major components comprising the seven current seismographic systems.

Table E1. Major components in seismographic systems comprising the SGBSN in the period 1987 through 1989. All seismometers have natural frequency, $f_n = 1.0$ Hz. The (analog) output of the discriminators is digitized on a PDP 11/34 computer, with sampling rate = 104.167 sps/channel.

KIND	SEISMOMETER	Motion	Amplifier/VCO	Discriminator
1	Mark L4C	vertical	Tricom 649	Tricom 642
2	Teledyne S13	vertical	Tricom 649	Tricom 642
3	Teledyne S13	vert., horiz.	Teledyne Geotech 42.50	Teledyne 4612
4	Mark L4C	vertical	Teledyne Geotech 42.50	Tricom 642
5	Mark L4C	horizontal	Teledyne Geotech 42.50	Teledyne 4612
6	Teledyne S13	vertical	Teledyne Geotech 42.50	Tricom 642
7	Ranger RR-1	vertical	Teledyne Geotech 42.50	Teledyne 4612

Figure E1 shows the amplification curves (theoretical frequency response) for typical vertical-component (KIND=3) and horizontal-component (KIND=5) stations on Yucca Mountain, Nevada, with data telemetered to a PDP 11/34 computer in Golden, Colorado, that has 12-bit A-to-D converters with digital gain, 2048 counts per 5 volts input.

Figure E1. *Upper* curve, magnification (displacement response) for a typical seismographic system on Yucca Mountain, Nevada, with a vertical-component Teledyne-Geotech S13 seismometer and associated electronics (type = 3, amplifier gain = 84 dB), and digital-computer recording. *Lower* curve (dashed), magnification for north-south and east-west component seismographic systems on Yucca Mountain, Nevada, with horizontal-component Mark L4C seismometers and associated electronics (type = 5, amplifier gain = 60 dB), and digital-computer recording.

NOTES: All instruments are vertical-component unless otherwise noted. If one horizontal-component instrument exists at a site, it has north-south polarity; if two horizontals exist at a site, they have north-south and east-west polarities, resp. The polarity is suggested by the station name. A * in the final column indicates satellite-determined station coordinates. Elevations of stations with *'s in the final column were obtained using altimeters calibrated against nearest USGS benchmark. Locations are preliminary.

Appendix F

Input parameters to HYPO71

HYP071.FOR, version 1.001, was baselined for use by the Yucca Mountain Project, with CID YMP-USGS/GDD0001.02, on October 22, 1990. This version of HYPO71 requires a minimum of three input files, (1), a header file, containing crustal velocity information, weighting scheme information, iteration-controlling parameters, and I/O-controlling parameters, (2), a station file, containing most of the information shown in Appendix E, above, and (3), a phase file, containing P and S phase arrival times and information for determining earthquake magnitude. The data of item (1) are presented in Appendix E, and will not be repeated here. The data of item (3) are too bulky for inclusion in this report, but are available on request.

One of two header files is used, depending on the source zone. For most earthquakes occurring in the SGB, the file `nvhead.dat`, having the velocity model shown in Figure F1 (a) is input. For earthquakes occurring in the immediate vicinity of Yucca Mountain, the file `nvhead.ymt`, having the velocity model shown in Figure F1 (b), is input. Copies of these two files are shown on the next page. For meanings of the "Control Card" parameters, the reader should consult Lee and Lahr (1975).

The below lines are a listing of nvhead.dat, used as an input file to HYPO71.

In this file, a slightly different weighting scheme with respect to distance is invoked than in nvhead.dat, above. In the former file, weights taper from 1. to 0. in a linear manner for epicentral distances between 10 and 220 km. In the latter file, weights taper from 1. to 0. for distances between 5 and 90 km.

Figure F1. (a) Primary (P) and secondary (S) wave velocities as a function of depth (0.0 = sea level) for the standard model used to locate southern Great Basin earthquakes. The interface at 15 km is optional. (b) P and S wave velocities as a function of depth for the Yucca Mountain region, being an idealization of the model proposed by Hoffman and Mooney (1984).
